AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

AAEA Annual Meeting
Clemson University
Clemson, South Carolina
26–29 July 1981

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press. Inc., Worcester, Massachusetts, USA.

Second class postage paid at Ames, Iowa, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, James P. Houck, Department of Agricultural and Applied Economics, 332 Classroom Office Bldg., University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Ronald A. Schrimper, Department of Economics and Business, P. O. Box 5368, North Carolina State University, Raleigh, NC 27650

An Opportunity Cost View of Fixed Asset Theory and the Overproduction Trap

Marc A. Johnson and E. C. Pasour, Jr.

In fixed asset and exit barrier theories, durable asset valuation is based upon acquisition prices, yielding downwardly biased rate-of-return estimates and erroneous implications that excess resources become trapped in production when product price expectations fall. Conventional asset valuation based on opportunity cost shows that excess resource applications are incompatible with rational producer behavior. Market failure conclusions of overproduction trap models are shown to be unfounded. A review of recently published agricultural economics texts illustrates how use of fixed asset theory in the college classroom obscures the concept of choice-influencing cost and the rule of resource allocative efficiency.

Key words: entrepreneurial choice, fixed asset theory, opportunity cost, rate of return.

Two similar theories of the firm attribute "persistently low rates of return" to invested capital to an inability of the firms to remove "excess resources" from production. Fixed asset theory, developed by Johnson and his colleagues (Johnson 1958, 1960; Johnson and Hardin; Johnson and Quance; Johnson et al.), formalized by Edwards, and popularized by Hathaway, suggests that fixed resources were "trapped" in agriculture resulting in persistently low returns to resources applied in agriculture during the quarter century following World War II. Caves and Porter present a theory of exit barriers arising from applications of "inputs that can become attached to the firm and then command persistently low earnings because they are *durable* and *specific* to an activity of the company" (p. 40).

Fixed asset and exit barrier theories suggest that overcommitment of durable resources, indicated by persistently low rates of return, is an inherent feature of business activity. The purposes of this paper are to (*a*) review the conventional theory of resource adjustment to show that excess durable resources are incompatible with rational producer behavior when resource costs are measured conventionally as opportunity costs, (*b*) demonstrate that fixed asset and exit barrier theories yield downwardly biased rate-of-return estimates having erroneous implications for resource adjustment, (*c*) demonstrate the inappropriateness of using fixed asset theory to judge entrepreneurial efficiency, and (*d*) illustrate the extent to which fixed asset theory is used in current agricultural economics texts.

Resource Adjustment Theory

Conventional economic theory states that a profit-maximizing firm, satisfying second-order conditions and selling in a competitive product market, will apply a quantity of each resource i in the production of product j in period t just to equate the value of marginal product (VMP_{ijt}) and the marginal factor cost (MFC_{ijt}), i.e.,[1]

$$(1) \qquad VMP_{ijt} = MFC_{ijt}.$$

Use of a unit of a durable resource entails application of the unit for a period of time to contribute to the production of value. Anticipated marginal product generated by a durable item, as for nondurable items, is the anticipated, incremental output attributable to pro-

Marc A. Johnson is an associate professor and E. C. Pasour, Jr., is a professor in the Department of Economics and Business at North Carolina State University.

This is Paper No. 6509 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh.

The authors acknowledge the helpful suggestions of Duane F. Neuman, Richard K. Perrin, and Daniel A. Sumner.

[1] The conventional analysis assumes a single-period production cycle or, alternatively, that production and cost conditions facing the firm are the same in each period of the production cycle. Moreover, if the firm attempts to maximize wealth over time, single-period flows do not provide sufficient information to determine output choices for that period (DeAlessi).

duction with the item rather than without; this output multiplied by expected product price is the expected value of marginal product of the durable item.

Economic resource cost is conventionally defined as opportunity cost, the value of a resource in the best alternative use.[2] For resource units not owned by the firm, opportunity costs are measured as prices for nondurable items and as operating costs (C_{ij}) plus either rental rates or overhead costs for durable items. Overhead costs include depreciation (anticipated change in the value of the asset during the production period ΔV_{ijt}) and interest cost, rV_{it}, where r is the opportunity cost of capital per period and V_{it} is the value of the stock at the beginning of production period t. For a non-owned resource unit, V_{it} would be evaluated at acquisition price during the first production period. For resource units owned by the firm, opportunity cost of using a durable unit for a period is measured as operating cost plus an overhead cost based on either a salvage market comparison ($\Delta V_{ijt} + rV_{it}$, where V_{it} is evaluated at current salvage price) or an internal use comparison (the unit's value in production of another product within the firm less resource switching costs), whichever is higher.[3] Thus,

$$(2) \qquad MFC_{ijt} = C_{ijt} - \Delta V_{ijt} + rV_{it}.$$

Each unit of resource, owned or not owned, has a single-valued, expected opportunity cost at the moment of decision making, depending upon its position with respect to space, time, condition, and ownership. Costs of using different units may differ by transport, storage, conditioning, and transaction costs, respectively.

Substituting the definition of MFC_{ijt} in equation (2) into the resource adjustment rule of statement (1) shows that additional units of resource i will be applied to enterprise j in time t until[4]

$$(3) \qquad VMP_{ijt} = C_{ijt} + \Delta V_{ijt} + rV_{it}.$$

Subtracting noninterest cost components from each side and dividing by V_{it} reveals the rate of return on the investment of applying the marginal resource unit to enterprise j in time t,

$$(4) \qquad \frac{1}{V_{it}} (VMP_{ijt} - C_{ijt} - \Delta V_{ijt}) = r.$$

Application of a capital item to an enterprise must yield a rate of return equivalent to the opportunity cost of capital, r. Stated differently, a rational producer would not use input i to produce product j if its expected return were greater in another use. Consequently, rational producer behavior results in expected marginal economic rates of return to durable resources at least equivalent to the producer's opportunity rate of return.

Measurement of asset value, V_{it}, is critical to the conclusions of fixed asset and exit barrier theories, viz., that resources become trapped in production and yield rates of return less than the opportunity cost of capital. When deciding to adjust levels of resource use, each unit of resource will carry its own cost of use according to the active opportunity foregone for the unit in its existing position with respect to space, time, condition, and ownership. If an additional unit must be purchased from the market, V_{it} is evaluated at acquisition price. If an additional unit is drawn from a currently owned stock, V_{it} is evaluated either as net present value of the unit applied to another internal enterprise or as the market salvage value. When market acquisition price for a new unit exceeds market salvage price of an owned unit, it is quite possible for the expected rate of return to a marginal, owned unit to equal or exceed the opportunity cost of capital while the expected rate of return to a marginal, new unit falls below opportunity cost of capital. In this situation an owned unit would be attracted to enterprise j while a new unit would not.

Excess Durable Resources

The following sections present two theories which contend that durable resources are economically bound in production, resulting in excess resource applications and low returns on investment. In the next section, fixed asset theory is summarized briefly and its implication of overproduction and persistently low rates of return on investment is shown to be erroneous due to inappropriate measurement of resource cost.

---

[2] Opportunity costs are based on anticipations. Consequently, cost is necessarily a forward-looking *ex ante* concept (Buchanan 1969).

[3] Internal use of resource i in another enterprise, k, would affect the value of the resource V_{it}. The internal use value of the marginal resource unit applied to enterprise k is

$$V_{it} = \Sigma_t (VMP_{ikt} - C_{ikt})(1 + r)^{-t}.$$

[4] An inequality, $VMP_{ijt} \geq MFC_{ijt}$, could result in the event of a discontinuity in the MFC_{ijt} function, e.g., the firm having applied the last internally owned unit is required to enter the market for additional units which are positioned differently.

Fixed Asset Theory

The theory of asset fixity is distinguished from conventional production theory by focusing on a divergence between acquisition and salvage prices of "identical" units of durable resources. The fixed asset for the single variable input case is illustrated in figure 1. (Implications are similar for the multiple input case.) When product price is high (as indicated by VMP_1), the firm finds it profitable to obtain Oa units of X_1. According to the theory, if product price should fall later so that VMP_2 is relevant, X_1 becomes a fixed asset because VMP at quantity Oa lies between acquisition and salvage prices. The within-firm opportunity cost of the input (shown in fig. 1) is assumed to exceed the market opportunity cost, or salvage value. However, a fixed asset is defined to be one for which the acquisition value exceeds the VMP and the VMP exceeds the salvage value (Johnson et al.).

A firm with one or more fixed assets implies "overcommitment" of resources in the sense that the VMP for each of the fixed assets is less than its acquisition price. Because the VMP of the resource lies between respective acquisition and salvage prices, quantities of resources applied are fixed and no adjustment would be initiated. Producers continue to use amounts of inputs purchased earlier when higher product prices were anticipated. Thus, the conclusion of fixed asset theory is that there is an "overproduction trap."

The conclusion of fixed asset theory that excess resources are "trapped" in production can be traced directly to selection of acquisition prices of resources as a benchmark for equilibrium production. But, there is no reason to expect the opportunity cost of a resource once acquired to equal its historical acquisition price. The choice-influencing cost associated with the use of any resource is the value of the foregone opportunities. For a single-product firm, the opportunity cost of using a unit of an owned durable resource is the market salvage value. For a multiple-product firm, the opportunity cost of an owned resource is the value in the best alternative use, including external sale. Thus, historical costs cannot legitimately be considered opportunity costs.[5]

When owned assets are valued on the basis of opportunity cost, fixed asset theory no longer implies that resources are "trapped" in agriculture (i.e., that the VMP is less than cost for any asset in use). The VMP may be less than historical cost but, as stressed above, "past costs are lost costs" and are irrelevant for current decisions. The concept of trapped or excess resources is thus inconsistent with rational behavior because the entrepreneur would never knowingly use a resource where the expected VMP is less than the expected opportunity cost.[6]

If overproduction and excess resource applications are inconsistent with rational behavior, what is the basis for the alleged low returns to durable capital resources? The preceding analysis suggests that the fixed asset theory conclusion, that the VMP of a fixed resource is below resource costs yielding a persistently low return, is inherent in the inappropriate measurement of resource cost.[7] A difference between acquisition and salvage price, as shown by recent work in information and search theory, is to be expected for all resources and can be directly attributed to resource positioning and transactions costs (Akerlof, Stigler). For example, the fact that the market value of a tractor or combine a few

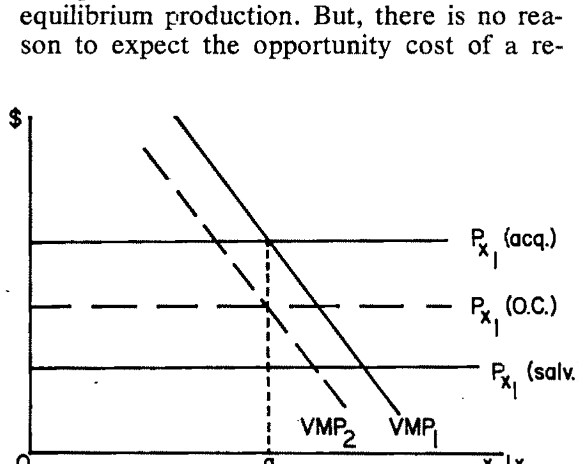

Figure 1. The single-input fixed asset case

[5] "There is no reason for supposing that the price one has paid for materials, or a figure derived from a calculation based on the prices one has paid, will give one the 'opportunity' cost of using materials. . . . On the one hand it ignores the expenses involved in reselling materials one has purchased—expenses which may be quite considerable; on the other hand it does not take into account the value of the materials if used for some other job" (Coase, p. 113).

[6] Where means and ends are assumed given to the decision maker, there is no scope for the entrepreneurial element. In a world of imperfect knowledge and costly information, where the entrepreneur is given information on neither ends nor means, estimating costs and benefits associated with alternative production strategies is a key entrepreneurial function (Kirzner).

[7] When opportunity cost is taken as the magnitude affecting entrepreneurial choice, it becomes clear that the decision maker would never knowingly sell a product below cost or use resources valued below cost, i.e., below the value of opportunities foregone.

days after purchase is substantially less than the price paid can be explained in terms of uncertainty and information costs. The fact that the current value is substantially below the acquisition price does not imply an overcommitment of resources. Furthermore, acquisition price in fixed asset theory is often measured as a historical purchase price, whereas salvage price arises from evaluation of salvage opportunities at a point later in time (Johnson 1958, pp. 77–78; 1960, p. 41). Consequently, the resulting measure of costs in fixed asset theory is upwardly biased relative to opportunity costs, yielding downwardly biased rates of return on invested capital relative to actual returns computed on the basis of opportunity costs.

Asset fixity theory also is used to make *ex post* evaluations of entrepreneurial decisions: "When a product price falls below prices anticipated at the time durable investments are made, an error of overproduction occurs" (Johnson and Quance, pp. 27–28). Here fixed asset theory as a resource-adjustment decision rule attempts to use accounting records (the objective historical record) to evaluate the astuteness of entrepreneurial decisions. However, entrepreneurial choice is concerned with expected costs and returns of future production, and the outside observer cannot obtain the data relevant to choice. Consequently, there may be little or no relationship between objectively defined costs and benefits and the evaluations that individuals place on alternatives in actual choice situations (Buchanan 1969b). Furthermore, it is not legitimate to use *ex post* data to evaluate entrepreneurial efficiency. To conclude that farmers are inefficient because they are not omniscient and make mistakes is to say little more than that the competitive equilibrium would be different if these were not facts of life (Demsetz). Entrepreneurial activity that is shrouded in uncertainty will always appear inefficient if judged against the perfect competition norm of static equilibrium theory, which implicitly assumes that there are no information and uncertainty problems. Thus, the entrepreneurial function is inherently subjective and the economist has no objective procedure (except for the survivor principle) to measure the efficiency of entrepreneurial activity.[8]

Although one cannot legitimately use derived equilibrium conditions as a norm against which to judge efficiency, the marginal principles of production theory are useful to the decision maker as a logic of choice. These principles can help the entrepreneur think in marginal terms and their use may produce "better" choices as evaluated by the decision maker's own standards (Buchanan 1969b).

Exit Barrier Theory

The exit barrier theory of Caves and Porter is similar to fixed asset theory developed by Johnson twenty years earlier. Emphasis is placed on the "limited salvage value" of durable specific assets. Caves and Porter purport to show that excess resources are "an element of market structure and *ex ante* determinant of market conduct and (thereby) performance" (p. 39). Exit barriers are alleged to result in persistently "subnormal" profits. Exit barriers arise because resources are "durably committed . . . to an activity of the company" (p. 40). Resources become durable because, once purchased, their value in use exceeds their salvage value. Durable assets include not only traditional, long-lived, specialized equipment but also working capital and intangible assets. Partly fabricated goods have a low salvage value relative to their value in finished form. Intangibles, such as trademarks, have a low salvage value because of limited markets. Labor with specific skills has a greater value in present use than in other uses not requiring the skill. All of these resources are considered durable in the sense that they are specialized to a particular firm and their value to the firm exceeds the salvage value. Durability, then, refers to a difference in value associated with the positioning of the resource rather than to an inherent physical characteristic; thus, a durable asset to Caves and Porter is a fixed asset to Johnson.

Rates of return on durable resources in the exit barrier theory are based on accounting data. Cost is taken to be the original (historical) purchase price less depreciation. The perceived exit barrier problem is one of low rates of return to durable assets. But rates of return, as in fixed asset theory, are measured in an *ex post* fashion by comparing value of marginal product with original purchase price. Cost as it

[8] As Coase suggests, "the correctness of the decision cannot be determined by subsequent events. If a businessman undertakes to do something which entails certain risks, he considers the choice of gain is worth the risk he runs, and whether ultimately he succeeds or fails has no relevance to this preference" (pp. 104–5).

motivates entrepreneurial choice, however, always deals with current alternatives. Historical cost provides no opportunities for choice. A correct measure of rate of return on resources used in any production process is to compare value of marginal product with current opportunity cost. The fact that the resource is "durable" to the firm suggests a marginal rate of return greater than the market interest rate. If the resource has a higher expected value in a competing use, the resource would not remain in its present use. The limited salvage value of durable assets, then, does not imply that inputs remain in use because of exit barriers; instead, the resources remain in use because the rate of return in the present use represents the most profitable alternative for these resources. Again, with appropriate opportunity cost measurement of resource cost, excess resources are incompatible with rational producer behavior.

"Excess Resources" in the Classroom

Excess resource arguments as a "convincing" foundation for low returns to capital in agriculture are prevalent in agricultural economics texts. The Caves-Porter exit barrier theory is quite recent, and its eventual impact on firm theory is uncertain. However, fixed asset theory has had an important influence in applied agricultural production and policy economics. The result is that students are presented unclear concepts of cost, investment evaluation, and entrepreneurial choice criteria. A review of several recently published agricultural economics texts reveals that, in at least three introductory agricultural economics texts and three agricultural policy texts, the notions of asset fixity are used to explain low returns to capital and labor resources applied to agriculture.

Fixed asset theory is used in the Goodwin and Halcrow (1980) introductory texts to explain low returns to durable resources as a problem of resource adjustment for the farm firm. On pages 312 and 318 of the Goodwin text, the difference between acquisition and salvage prices is evaluated following a lapse of time, and contraction of activity is described as "tortuous and painful because he cannot salvage these fixed assets at their full value." Halcrow implies that the choice of prices to use in investment evaluation and profit measurement is arbitrary:

> The net return from the use of a tractor may be below a normal rate of return based on the acquisition price, P_A, but well above the liquidation price, P_o. Many farmers who bought tractors and equipment in 1973–1975, for example, when grain prices were high, were able to justify their purchases on the basis of those prices. But in the late 1970s when grain prices were lower, those farmers were unable to make a normal profit, based on P_A, although the price of grain was well above their close-down level. (Halcrow 1980, pp. 214–15)

These conclusions need not bear normative sadness if resource allocation and cost measurement rules are based on opportunity costs. The fact that resources become "fixed" may be interpreted to mean that resources continue to be allocated in the activity yielding their highest return. Resources are moved when there are greater opportunities elsewhere. The fact that resources might have been better placed originally is irrelevant from the standpoint of current allocative efficiency. Stated differently, sunk costs are irrelevant to current decisions. Furthermore, mistakes are inevitable when operating under real world conditions of risk and uncertainty.

The Doll-Rhodes-West general agricultural economics text filters out the best of what asset fixity theory has to offer. The theory is used only for questions of farm resource adjustment at a moment in time. Acquisition and salvage prices are evaluated simultaneously and, at any moment, a decision maker chooses among three options: to expand, to contract, or to continue unchanged.

Fixed asset theory is used in policy discussions to explain low levels of agricultural prices and irreversible aggregate, agricultural supply functions. The policy chapter of the Wilcox-Cochrane-Herdt text suggests that resource fixity results from the fact that "land and sunk capital cannot be moved" (p. 296). The authors imply that this is a reason for low agricultural prices, without stating that rates of return in agriculture, based on current asset values, still may be competitive with returns on assets of comparable risk.

The Halcrow (1977) agricultural policy text uses asset fixity to explain farm labor immobility and subsequent supply inelasticity in agriculture. Agricultural labor is alleged to be fixed in agriculture because these individuals do not have opportunities valued as highly as the acquisition price necessary to attract new workers to agriculture. The logic is not complete for judging the opportunities of one

group against the opportunities of another. Doll, Rhodes, and West correctly define labor resource fixity as a situation where returns to labor in the current activity exceed opportunity returns, with no mention of an irrelevant acquisition labor price.

Tweeten's agricultural policy text presents asset fixity as one of three theories to explain "why . . . resources (don't) move out of agriculture at a rate sufficient to bring equilibrium returns" (p. 178). Tweeten discounts the importance of asset fixity to the farm problem not by rejecting the theory but by showing that each resource group involved in agriculture is not very durable or has salvage prices only slightly below acquisition prices. The irrelevance of acquisition prices in computing the rate of return to agricultural resources in place is not discussed.

The O'Rourke policy text presents Johnson-Hathaway asset fixity theory as an explanation of slow adjustment in agriculture to lower prices. However, as suggested above, the seemingly slow adjustment to price decreases is more likely a reflection of competitive returns to resources valued on the basis of opportunity costs rather than an indication of low returns as suggested by asset fixity theory.

Use of fixed asset theory in agricultural policy discussions can be summarized as implying that the supply function is not reversible and independent of the direction and duration of changes in product prices (Plaxico; Vincent, chap. 7). However, supply analysis based on the Marshallian distinction between "fixed" and "variable" factors yields a similar result, viz., supply curves are more elastic the longer the length of run and the supply function is not reversible (Becker, pp. 79–83). This relation between duration and cost occurs even in the absence of uncertainty about the time period of demand changes. Thus, the supply response conclusions drawn from the fixed asset model are not unique.[9]

Conclusion and Implications

The theories of asset fixity and exit barriers both have been formulated to address the alleged problem of persistently low rates of return to invested capital. In estimating rates of return, both approaches use (historical) acquisition costs rather than opportunity costs applicable at the time when rates of return are estimated. Both approaches focus on resource allocation where resource values in use have fallen below acquisition prices, but not below salvage values, and conclude that these resources are trapped in their current use while yielding a low rate of return. However, the relevant rate of return for any asset should be based on the value which motivates entrepreneurial choice, the current opportunity cost. When rates of return are evaluated on the basis of current opportunity costs, the implications are quite different—resources are shown to be rationally attracted (retained) in their current use rather than being trapped there, and rates of return are competitive with current alternatives.

A difference between acquisition and salvage prices of assets, as shown by the Caves-Porter exit barrier theory, is not unique to the agricultural sector. In the real world markets, information is scarce and costly and salvage values for assets once acquired are generally lower than acquisition costs. Fixed asset theory can be useful in stressing the role and importance of information and transactions costs in explaining differences between costs of inputs positioned differently in time or space. Moreover, the theory can contribute toward an understanding of why the supply function, whether firm or industry, is not reversible and is more elastic the longer the length of run. However, the appropriate focus of fixed asset theory is on the reasons for the divergence between acquisition and salvage prices rather than on resources being "trapped in use.' The implication of market failure, in the sense that resources are misallocated, is not warranted in either theory of excess durable resources.

A difference between acquisition and salvage values does not imply that current asset markets are inefficient. While acquisition and salvage values are equal in a "perfect market," it is inappropriate to measure the efficiency of resource markets against the perfect market norm which assumes that decision makers have perfect knowledge and that positioning costs are zero. When measured against the perfect market norm, all markets will appear to be "inefficient" (Demsetz). If a difference between acquisition and salvage value is

[9] "While the conceptual model is useful in categorizing inputs, the conclusions drawn from the model are no different from those reached by other agricultural economists. Namely, the lack of profitable alternative uses for certain inputs such as family labor limits the response of supply to a fall in farm prices, at least in the short run. and especially in periods of general depression" (Tomek and Robinson, p. 360, 61).

taken to imply resource fixity, then virtually all real world markets are characterized by asset fixity. Theories of excess durable resources based on a difference between acquisition and salvage values hinder students from acquiring a precise concept of choice-influencing cost and of the rule for resource allocative efficiency under real world conditions where information and resource positioning are costly.

The entrepreneurial function concerned with exploiting profit opportunities has not been handled adequately by excess resource models or by maximization models generally in economics. If one assumes that the decision maker has perfect knowledge, then there is no scope for entrepreneurial activity. Moreover, if it is recognized that the entrepreneur operates in an atmosphere of risk and uncertainty, it is inappropriate to measure performance against a model which assumes away these problems. Entrepreneurs inevitably will make mistakes from the viewpoint of hindsight or an omniscient observer when dealing with the uncertain future.

Price Distortions in Agriculture and Their Effects: An International Comparison

Malcolm D. Bale and Ernst Lutz

The central thesis of this paper is that agricultural pricing policies pursued by developing countries produce effects which are diametrically opposite to those produced by the pricing policies of many developed countries, and that the policies of both are costly in terms of global welfare. In general, the agricultural sector in developing countries is heavily taxed while that in the developed countries receives substantial price protection. The effects of agricultural price distortions on output, consumption, trade, and rural employment are estimated for nine countries. In addition, the effects of price distortions on the distribution of income between producers and consumers, on government revenue and foreign exchange, and the net social losses of the policies are calculated.

Key words: agricultural policies, price distortions, social costs, trade intervention, welfare analysis.

While in some parts of the world agricultural policy must deal with the problem of surpluses, in other parts of the world—particularly in developing countries—agricultural output is often insufficient to cover basic food needs. The reasons are many and varied, ranging from distribution and production techniques to political intervention at various levels in the global agricultural complex. While the most important reasons for inadequate agricultural output are difficult to ascertain, T. W. Schultz, in the first Elmhurst Memorial Lecture to the International Association of Agricultural Economists, left no doubt as to his ranking of the causes. He stated that the level of agricultural production depends not so much on technical considerations, but in large measure "on what governments do to agriculture." (See also Schultz 1977, 1978.)

It is well known that governments intervene in the agricultural price-setting mechanism in many different ways and for assorted reasons. For example, export taxes on agricultural products provide government revenue and help keep domestic prices low; product price supports in developed countries maintain farm incomes and lead to surpluses which in turn find their way to developing country markets often on concessional terms, further depressing domestic farm prices; and agricultural inputs are frequently either taxed or subsidized. Yet, the magnitude of the effects of these policies on agricultural output, income distribution between producers and consumers, efficiency, and on rural employment is often not fully appreciated.

The ways in which governments can intervene to alter market incentives in agriculture can be classified in three ways, based on their impact on output (after Schultz 1978). First, there are economic policies that are neutral with respect to the opportunity cost of agricultural production. Second, there are those where agricultural production is overvalued. And, finally, there are policies through which agricultural production is undervalued. Only a few countries meet the first classification (they are not identified here). Typically, high-income developed countries fall into the second category. In this study, we examine Japan, West Germany, France, and Great Britain, countries where levies are placed on grain imports, where imports of sugar, meat, and dairy products are restricted by quotas, and where, in the case of Japan, rice is greatly overpriced relative to world levels. The immediate consequences of these policies are overproduction and underconsumption of ag-

Malcolm D. Bale and Ernst Lutz are economists with the Development Policy Staff of the World Bank.

The authors acknowledge helpful comments on an earlier version of this paper by Willis Peterson, Alan Harison, and an anonymous reviewer.

ricultural output. The third category typically is made up of low income developing nations. Here, as examples, we examine the pricing policies of Thailand, Egypt, Argentina, and Pakistan, where export taxes and price controls often undervalue agricultural output, resulting in underproduction. Many of these nations produce insufficient foodstuffs, and they cannot afford to forego production opportunities. In addition, we consider the case of Yugoslavia, classified both as a developing country and as a centrally planned economy.

This paper discusses government intervention in the determination of agricultural product prices, drawing on welfare theory to quantify the economic impacts on output, income distribution, efficiency, and employment. The general theme is that the agricultural policies pursued by developing countries produce effects which are diametrically opposite to those of many developed countries, and that the policies of both are costly in terms of global welfare. (A recent study which addresses the developing country side of this question in a somewhat different manner is Peterson.) The paper begins with a description of the theoretical model on which the analysis is based and then continues by detailing the data sources; results are presented in the next section, followed by some concluding thoughts.

Method and Theoretical Basis

The results of the paper are derived using standard partial equilibrium comparative static analysis in the Marshallian economic surplus framework. The method is well known for both its usefulness and limitations. Details on this approach are not presented here, but the reader is referred to Currie, Martin, and Schmitz for an excellent review of the concept, to Bale and Greenshields for an application, and to Lutz and Scandizzo for a review of other studies.[1] In this paper, the real and pecuniary effects of agricultural price distortions are analyzed using nominal protection coefficients (NPCs) to measure the disparity between domestic output prices and border prices. Typical causes of price distortions evaluated here are producer price supports, tariffs, quotas, export taxes, and overvalued exchange rates. Input subsidies for irrigation water, fertilizer, and credit are not considered because of the difficulty of obtaining cross-country data and because of the impossibility, in the case of water, of evaluating a "market" rate when its costs and lifetime are unknown. In each case, the intervention drives a wedge between the domestic price and the world or "border" price. Domestic prices are defined as the prices at farm and consumer levels, converted into U.S. dollars, using shadow exchange rates; border prices are the existing "world" prices at the same point in the marketing chain (i.e., the small country assumption has been used). Border prices are used as the point of reference for the evaluation because they represent the opportunity cost of the traded commodities.[2] They are also conveniently available as they are observed in the international marketplace. Nominal protection coefficients provide a measure of the disparity between domestic prices and international prices, and are defined as

$$NPC = 1 + \frac{P_d - rP_w}{rP_w} = \frac{P_d}{rP_w},$$

where P_d is domestic price, P_w is border price, and r is the equilibrium exchange rate.

The basic analytic structure of the model is represented by equations (1) through (7):

(1) net social loss in production

$$NSL_p = 1/2\,(Q_w - Q)\,(P_w - P_p) = 1/2\, t_p^2\, n_s\, V,$$

[1] While the method is widely used, it is not without its detractors. There is, in fact, a considerable body of literature and an ongoing theoretical debate regarding the appropriateness of using the underlying utility functions in evaluating welfare gains and losses across individuals or countries. The debate centers on whether consumers' surplus analysis provides a measure of benefits and losses in terms of the "compensating variation" and the "equivalent variation" in the contemporary Hicksian form. Bergson clarifies this debate, finally noting that "despite theoretical criticism, practitioners have continued to apply surplus analysis through the years . . . that must say something about the usefulness of such analysis" (p. 43). Willig, in a later article whose "purpose is to settle the controversy surrounding consumers' surplus and, by so doing, to validate its use as a tool of welfare economics," demonstrates theoretically that "consumers surplus is usually a very good approximation to the appropriate welfare measures" (p. 589).

[2] We recognize that the general equilibrium effects of removing price distortions on a global basis would alter border prices and therefore alter the magnitude of the distorting effects. However, it is extremely difficult to estimate "shadow-free market prices" in a first-best world, and we do not suppose that we will ever be operating in a first- or even second-best environment.

In our analysis there are some cases where the use of the small country assumption may have introduced a bias into our results. Both for exporting countries and for importing countries our method may overestimate the true effects. This may apply to rice in Thailand, cotton in Egypt, wheat in Japan and wheat in France. When some large countries are being considered simultaneously, the effects can be additive or they can cancel each other out. For example, while the export taxes of some developing countries may increase the world market price the import tariffs of some industrialized countries may depress it.

(2) net social loss in consumption

$$NSL_c = 1/2\ (C_w - C)\ (P_c - P_w) = 1/2\ t_c^2\ n_d\ W,$$

(3) welfare gain of producers

$$G_p = Q\ (P_p - P_w) - NSL_p,$$

(4) welfare gain of consumers

$$G_c = C\ (P_w - P_c) - NSL_c.$$

(5) change in foreign exchange earnings

$$dF = -P_w\ (Q_w - Q + C - C_w),$$

(6) change in government revenue

$$dG = (NSL_p + NSL_c) - G_p - G_c = -(1) - (2) - (3) - (4), \text{ and}$$

(7) change in rural employment

$$dL = dQ\ L/Q,$$

where Q_w is production at world prices; Q, production at domestic prices; P_w, border prices; P_p, price faced by domestic producers; P_c, price faced by domestic consumers; t_c and t_p, proportion of tariff in domestic price at the consumer (t_c) or the producer (t_p) level; n_s, elasticity of domestic supply; n_d, elasticity of domestic demand; V, value of production at P_p; W, value of consumption at P_c; C_w, consumption at world prices; C, consumption at domestic prices; and L/Q, labor/output coefficient.

Because border prices are used as the basis for comparison, the domestic prices used must correspond to the same point in the marketing chain. In calculating NPCs, farmgate prices in developing countries have been adjusted upward to take into account different transportation costs and marketing margins to the central market. (For specific details, see country case studies referenced.) The prices used may therefore be described as wholesale prices. For industrial countries, wholesale prices as reported were used in the study.

In measuring the cost of protection, the use of equivalent tariff levels—which are necessary for agricultural products facing many nontariff barriers—means that production and consumption effects are measured at the wholesale level rather than at the farm and retail levels. This may result in the underestimation of the welfare costs. For example, consider the following demand function:

$$Q = \alpha - \beta P_r, \text{ where} \tag{8}$$

$$P_r = P + f(P), \text{ and} \tag{9}$$

$$dP_r = dP\,[1 + f'(P)], \tag{10}$$

where P_r is retail price, P is wholesale price, and $f(P)$ is marketing margin. The measured change in consumers' welfare is

$$dP\ (C - 1/2dQ), \tag{11}$$

where C is consumption at domestic prices. The actual change in consumers' welfare is

$$dP_r\ (C - 1/2dQ). \tag{12}$$

From equation (10), if $f'(P) = 0$, that is, if the marketing margin is constant, then the welfare estimate is unaffected by the choice of price. If $f'(P) > 0$, implying that markups increase as price increases, then the welfare effect is understated. The same exercise may be performed on the producer's side with the same results. Thus, where it can be assumed that marketing margins are constant, no bias occurs. At a practical level, the use of a wholesale price can be justified on several grounds. Many products undergo transformation into different products between the wholesale and retail level. Thus, a single retail price does not exist for the product. This may be true for wheat, barley, maize, and beef in many countries. In some developing countries, where grains are used in households, wheat is subsidized such that wholesale and retail prices are similar. Given these factors, we have been forced to compromise the ideal and to use what is available.

Data Sources

The base year of the analysis is calendar 1976. The *FAO Production Yearbook* was used as a source for production levels; imports and exports were obtained from the *FAO Trade Yearbook*. Given the unavailability of data for consumption and stocks, particularly for developing countries, consumption was derived from production and trade data, assuming the levels of stocks remained unchanged. Supply and demand elasticities were taken from Rojko et al. In all cases they are long-run, general equilibrium elasticities, although here we suppress the cross-price terms.[3] Because elasticity estimates differ widely from re-

[3] The cross-price terms are small and cannot be used in standard welfare analysis. We use the Rojko elasticity measurements because they provide a consistent set of elasticities for the commodities and countries used here. Since elasticity estimates can differ we have used range analysis.

searcher to researcher, and because we wished to demonstrate the sensitivity of the results to changes in elasticities, the supply and demand elasticities presented in table 1 are ±0.5 times the point estimates given by Rojko et al.

Nominal protection coefficients for developing countries were derived from detailed country case studies by Bertrand (Thailand), Cuddihy (Egypt), Gotsch and Brown (Pakistan), Reca (Argentina) and ULG Consultants (Yugoslavia). In order to make adjustments for currency overvaluation, the nominal protection coefficients were multiplied by the following ratios between the shadow exchange rate and the official exchange rate of the different countries as estimated by the World Bank: Argentina, 0.8; Egypt, 0.69; Kenya, 0.76; Pakistan, 0.91; Portugal, 0.83; Thailand, 0.88; and Yugoslavia, 0.98. Shadow exchange rates for developed countries are not estimated and are here assumed to be the same as market rates.

The nominal protection coefficients for developed countries were calculated from data of the International Wheat Council, International Sugar Organization, U.S. Department of Agriculture (1979), and the World Bank. Note that despite the Common Agricultural Policy of the European Economic Community (EC), NPCs of members are not identical. This is due to the "Monetary Compensatory Amounts" (MCAs) and "green" currencies, because of which internal EC exchange rates in agriculture differ from official exchange rates.

Labor/Output Coefficients were constructed from Bartsch, Palacpac, International Cotton Advisory Committee, U.S. Department of Agriculture (1978a, b), United Kingdom Ministry of Agriculture, Forestry, and Fisheries, and the European Communities Commission. In the case of developing countries, marginal labor/output coefficients were derived from a labor-intensive technology, such as hand harvesting with a bullock-drawn cart and hand threshing. Average coefficients are simply the average of coefficients taken from two or three different production techniques on irrigated and nonirrigated farms. In developed countries, only average coefficients were available. Marginal coefficients in these countries were assumed to be 1.5 times the average coefficients.[4] The conversion rates of man-hours to full-time worker equivalents, in hours per year, are: France, 1,964; Germany, 2,315; United Kingdom, 2,269; Japan, 2,450; Yugoslavia, 2,450; and developing countries, 2,980. The basic data used in our analysis is shown in table 1.

Our use of a rather simplistic model of rural employment, and its change relative to output, is based on an input-output view of agricultural production. This approach was used by Thorbecke, where the following equation was estimated:

$$E_A = \alpha_0 + \alpha_1 Q_A,$$

where E_A is employment in agriculture and Q_A is agricultural output. Such an approach obviously produces a constant labor-output coefficient, a shortcoming of any linear system, which in turn implies a constant marginal physical product of labor. While more sophisticated models have been developed and estimated by others (for example, Todaro), we have assumed constant input-output coefficients.

Results

We first consider the merchandise effects.

Production, Consumption, and Trade Effects

Agricultural pricing policies in developed and developing countries are significantly different. While prices for agricultural commodities in developed countries generally have positive rates of protection, in developing countries commodities are often taxed through price intervention measures. As a result, the levels of agricultural production in industrialized nations are higher than they would be without intervention, whereas agricultural output in less developed countries is significantly smaller than what it would be in the absence of distortions. In the high elasticity case, France and Germany, for example, are producing an increment of 4.3 and 2.8 million tons of wheat, respectively, because of price protection, whereas in Argentina and Pakistan, production is discouraged, with a resulting estimated decrease of 7.0 and 1.3 million tons, respectively (table 2).

[4] The assumption that marginal coefficients are 1.5 times the average coefficient for developed countries is broadly consistent with the Hayami and Ruttan estimate of 2.5 for a sample of developing and developed countries. Clearly the inclusion of highly labor intensive techniques in developing countries makes the Hayami and Ruttan estimate higher than ours.

On the other hand, the picture is reversed with respect to consumption. Developing countries consume more and developed countries less than they would in the absence of price intervention measures. Thus the pricing policies clearly have a beneficial effect in terms of providing more food for the nonagricultural population in developing countries. However, assuming that this result is one of the policy objectives of price intervention, it is achieved at the expense of the agricultural sector.

The effects on trade are merely a combination of the effects on production and consumption, since stocks are assumed to be constant. In general, we find that the pricing policies cause a reduction in the exports of developing countries (for exported commodities with NPCs smaller than 1) and a lessening of imports by the industrialized nations (for imported commodities with NPCs larger than 1). In the case of imports by developing countries with NPCs of less than 1, these imports are increased by the sum of the absolute values of the effects on production and consumption. Such a situation implies government subsidies, for example, in Egypt for wheat and maize. (Parts of the imports may not be subsidized directly by the government of Egypt but may be the result of shipments at concessionary terms.) On the other hand, export commodities with NPCs larger than 1 imply that dumping is taking place and that export subsidies are necessary to bridge the gap between the internal price and world market price. All five commodities analyzed for France show the effects of this policy.

On the basis of a small sample of countries it is difficult to determine what the aggregate effects of agricultural policies are at the world market level. Even for a standard case in which developing countries are exporters using export taxes and where developed countries are importers with positive rates of protection, the sign of the impact on the world market price cannot be determined a priori, because both net exports and net imports are being reduced at the same time. Hence, it would be necessary to analyze the policies of all trading countries simultaneously for a particular commodity before the world market price impact could be estimated.

Employment/Migration Effects

The process of economic development typically is associated with internal migration from the primary sector in rural areas to industrial and service sectors in urban centers. Economic theories on internal migration attribute this shift as a response to differences in employment opportunities between regions. Potential migrants evaluate costs and benefits associated with relocation and make their decision accordingly. A primary determinant in their decision is the relative income opportunities in rural versus urban locations (Falaris). In spite of (or because of) massive development efforts over the last decade, rural poverty persists in many parts of the world,[5] and recent work has demonstrated that low real-income levels of farm households have in some cases declined (Rajaraman) at the same time that various price-support measures are maintaining farm incomes in other parts of the world.

A common explanation for rural poverty is that agricultural productivity is low because of tenancy arrangements and limited access to modern inputs and techniques such as controlled irrigation, chemical fertilizers, pesticides, mechanization, new varieties of crops, credit, and extension services. Such explanations ignore the effect that product prices have on agricultural productivity and, therefore, on employment and migration. Here we attempt to quantify the extent to which product prices that are undervalued contribute to a suboptimal rural population and the extent to which product prices that are overvalued contribute to a larger-than-optimal rural population.

In Table 2 we present four estimates of the impact of price distortions on agricultural employment. Two are based on average labor/output coefficients, using production changes calculated from high and low supply elasticity estimates. The other two are calculated using marginal labor/output coefficients where production changes are based on high and low supply elasticities. There are three reasons for presenting the results in this manner. First, we wish to demonstrate the sensitivity of employment to changes in assumptions. Second, labor coefficients tend to be rather gross estimates, as they are derived from numerous secondary sources that use different assumptions and they typically vary by more than 100% within developing countries according to different production techniques for the same crop. Our results may be regarded as captur-

---

[5] ". . . the most promising attack on employment problems in developing countries is in efforts to redress the present urban bias in development strategies" (Edwards).

ing the upper and lower bounds of employment changes. Third, it can be argued that under a regime of distorted prices, marginal operators will be displaced or expanded in response to price changes. Thus, marginal labor/output coefficients are more appropriate for estimating impacts on agricultural employment.

Referring to the developed countries in table 2, we see that existing agricultural pricing policies cause significant numbers of workers to remain in agriculture. Japanese rice-pricing policies are particularly significant, causing from between one-half of a million workers (low supply elasticity, average coefficient) to 2 million workers (high supply elasticity, marginal coefficient) to stay in agriculture. As a proportion of farm population, the numbers are large (2.1% to 9.6%); expressed as a proportion of total population (0.4% to 1.9%), the numbers are still significant. In the European countries presented here, the number of workers retained in agriculture is somewhat smaller, both absolutely and relatively. For example, in France, if free-market prices were to prevail for all five commodities, between 52,987 and 241,200 workers in an agricultural labor force of 8.6 million would be displaced.[6] In terms of the total work force, the proportion is 0.16% to 0.75%. While this percentage may seem rather small, it is nonetheless significant.

In developing countries, agricultural price distortions have the effect of reducing farm employment from that which would exist under free market prices. In general, the absolute value of the effects on employment is larger for developing than for developed countries, partly because of the labor-intensive production methods used in developing countries. The numbers suggest the extent to which price distortions create unemployment and stimulate migration. Using the high supply elasticity and marginal labor coefficients in Egypt, for example, the total reduction in agricultural employment for the four commodities is 1.15 million workers, or around 5% of the rural population. Employment in rice production accounts for a large portion of this. No doubt the numbers would be considerably larger if secondary (multiplier) effects were considered and if all commodities were covered.

Unemployment and rates of rural-to-urban migration greater than the rates of urban job creation are serious problems in developing countries. While overt unemployment is pronounced in urban centers, disguised unemployment is prevalent in rural areas (Todaro). Thus, any policies that contribute to unemployment or underemployment, such as agricultural pricing policies, need to be examined carefully. The conventional lay wisdom that if prices for farm products were to be increased in developing countries, poor people would be hurt, needs to be scrutinized. Many of the poor are rural poor or former rural residents who have migrated to urban areas in search of better employment opportunities. Higher agricultural prices would assist them if they were to remain as farmers, landless laborers, or farm-related workers. Viewed in a longer-run dynamic context, as farmers and farm laborers realize higher incomes, their demand for urban-produced goods and services will increase, so stimulating employment in urban areas.[7]

Welfare Effects

Our results indicate that the economies of the countries analyzed incur large annual welfare losses due to a misallocation of resources resulting from the existing agricultural pricing policies (table 3). The losses depend linearly on assumed elasticities and quadratically on the size of the price distortion as measured by a proportional tariff rate. Total net social losses are the sum of net social losses in production and in consumption. They range from U.S. $26 million for the United Kingdom (the low elasticity case) to U.S. $4,119 million for Japan (the high elasticity case). Even though the sample of commodities used in this analysis is small, it is interesting to compare the estimated welfare losses to the GNP of the countries.[8] The results show that in comparison with economic output, distortions are generally more costly to developing countries than to industrialized nations (table 4). Compared to agricultural gross national product (GNP), however, the comparative losses of the different countries are somewhat more evenly distributed when the importance of the agricultural sector in the total economy is taken into account.

The results have been obtained from a par-

[6] We do not wish to render the labor estimates useless by presenting numbers which have such a large variance, but we do want to present realistic upper and lower bounds.

[7] We are indebted to Willis Peterson for suggesting this point.

[8] By selecting only four or five major agricultural commodities here, we clearly underestimate the effects of the price distortions in the agricultural sector. Thus, our figures represent lower bounds of the true effects.

tial equilibrium model and hence capture only partial effects. However, it is clear that distortions of the size discussed here would have repercussions in other sectors of the economy as well. Thus, a general equilibrium analysis would produce estimates of social costs larger than those estimated here.

As our results in table 5 indicate, the most sizeable effects of the different agricultural policies are the welfare transfers between consumers and producers. While the farm sector in the developing countries studied was taxed from about $700 million to about $2 billion annually, the producers in developed countries received large transfers due to the protectionist policies. In Japan, where the average rate of protection is the highest, farmers gained between $2.6 and $5.1 billion for the total of the five major commodities analyzed. (See Bale, who estimates the producer gain to farmers for these products, except sugar, at $5.29 billion in 1975/76.) Consumers in developed countries incurred large welfare losses because of price protection whereas the consumers in developing countries generally gained from this type of price intervention. Relating the magnitudes of the welfare transfers to the size of the social losses, it is apparent that the transfers are far more sizeable than the deadweight losses.

Our results indicate that, with the exception of France, governments in all countries received increased revenues from their interventionist policies. These results are based on the implicit assumption that the entire price distortion is attributable to taxes (or subsidies). In reality, however, quantitative restrictions also are used, and unless the quotas are auctioned, the quota recipient gets the revenue. So, in general, our results tend to overestimate government revenues. Exceptions are those countries that import commodities with NPCs of less than one (e.g., wheat in Pakistan), in which case our method assumed implicitly that the entire distortion is due to government subsidies. To the extent that imports at concessionary terms are involved, our results underestimate actual government receipts.

The effects on foreign exchange earnings are again clearly divided according to different levels of development. While industrialized nations gained foreign exchange through protectionist policies, developing countries lost foreign exchange earnings. This is particularly serious in that foreign exchange availabilities represent a major bottleneck for developing countries in their efforts to increase growth and alleviate poverty.

Limitations

Two caveats need to be made in order to insure proper interpretation of our results. First, the results are based on only one year—1976. Second, in certain cases the quality of the data is uncertain and some personal judgments were required. Because of the uncertainties involved, range analysis was used to ascertain the sensitivity of the results to different data input. We regard the results as providing orders of magnitude rather than exact measures. As indicated by the range analysis, the qualitative conclusions are stable with respect to different elasticity assumptions. Methodological questions were addressed in a previous section.

Table 5. Monetary Effects of Price Distortions 1976 (in '000 U.S. Dollars)

Conclusions

What emerges from this paper is the vital role that farm product prices play in achieving optimum output and growth in productivity. Because "incorrect" price signals are being given to farmers, full potential in terms of allocation, production, and consumption is not being realized. In many cases, the estimated changes in production have greatly altered trade patterns, in some cases causing importing countries to become self-sufficient, in other cases causing "would-be exporters" to become importers. Particularly the magnitude of income transfers but also that of the efficiency losses (net social losses) are significant, both as an absolute number and as a proportion of national and agricultural income. The effects of price distortions on rural employment, while perhaps less impressive than the welfare losses, are nonetheless serious, given the high unemployment rates in developing countries and the political sensitivity of agricultural employment in developed countries. Since we have not considered distortions in the input markets our analysis may overestimate or underestimate the true welfare effects depending on the nature of the input distortion (subsidies or taxes) and whether the nominal protection coefficients are greater or less than one.

The ultimate question about agricultural pricing policies is their long-term dynamic effects. In this paper we have quantified the static effects. Our model (and the state of technology of our profession) did not allow us to estimate accurately the effects on income and industrial growth, adoption of technology, investment in agriculture, social consequences, and others. While it is politicians and not agricultural economists who make the decisions for governments, our profession plays a vital role in defining and quantifying the issues involved, and in passing these findings to appropriate officials. Our hope is that this paper is in keeping with that tradition.

A Multicommodity Analysis of Trade Policy Effects: The Case of Nicaraguan Agriculture

Daniel Fajardo, Bruce A. McCarl, and Robert L. Thompson

Agricultural trade policies for a small country are analyzed, using a simple, multicommodity, quadratic programming, agricultural sector model. The policy conditions simulated include (*a*) quantitative trade restrictions given an uncertain world market, (*b*) export taxation, and (*c*) import subsidies. The multicommodity, sectoral-wide coverage permits analysis of the factor-product market linkages and enables identification of the distributional consequences.

Key words: Nicaragua, quadratic programming, sector modeling, trade policy, uncertainty.

Agriculture must play a number of competing roles in a developing country. As well as producing food for a growing nonfarm sector, it also must play a large role in generation of foreign exchange, employment, and gross national product (GNP). This can result in a number of policy conflicts. On the one hand, governments frequently attempt to hold food prices artifically low to protect the real income position of urban consumers. On the other hand, farmers must be provided adequate incentive to produce both domestic food and exportables. One area in which conflict does arise is trade policy.

International trade theory suggests that the optimum trade policy for a small open economy under certainty is free trade. Any distortion of domestic relative prices away from the international terms of trade results in a social welfare loss in that country. However, given an uncertain and variable world market, the welfare benefits gained from trade may be accompanied by less stable domestic markets. Many less developed countries (LDCs) have adopted restrictive trade policies to dampen the effects of world price uncertainty on their domestic economies. The demands of the LDCs in the current trade discussions for world commodity price stabilization (Warley) are partly in response to volatile world prices.

Most empirical studies of trade policy and other costs of protection have been carried out in a partial equilibrium framework, one commodity at a time, with all other prices and real income held constant. Even when carried out for a number of commodities in the same economy, the analyses usually are done one commodity at a time, ignoring the interrelationships (simultaneities) among the commodities in both production and consumption (as in Bale and Greenshields). Factor market and functional income distribution adjustments, which often are ignored, are in reality just as often the crux of the argument in trade policy considerations. The objective of this paper is to present and illustrate the use of a simplified model of a small, open economy for obtaining approximate estimates of the effects of trade and policy distortions. The model encompasses production of multiple commodities from multiple factors. A second objective of this paper is to examine the effects of trade restrictions on domestic market stability.

To achieve these objectives a simple, open, fifteen-commodity, quadratic programming model of the Nicaraguan agricultural sector is constructed. The model includes farm production, processing and trading activities, domes-

tic demand, labor and land supply, credit, and other input use. Three policy simulations are carried out with the model, and the effects on all of these variables are estimated. First, because Nicaragua imposes formal and informal quantitative restrictions on trade, which cut the link between domestic and world market prices, the effects of removing these quotas are simulated. Further, because one of the objectives of imposing quantitative restrictions is domestic price stabilization, the impact of the existing restrictions and their removal is simulated with eight different years of world price data. Second, the effects of imposing an export tax such as was used to generate tax revenue following the 1972 earthquake are simulated. Third, the effects of agricultural input subsidies are simulated. The comparative statics effects on equilibrium quantities and prices in both product and factor markets and distributional effects are presented.

Background

Like many LDCs, Nicaragua is a small, open economy which derives a large portion of its foreign exchange earnings (60%) from agricultural exports; yet it does not export a sufficient quantity of any one product to be able to affect the world terms of trade. The agricultural sector can be dichotomized into two production subsectors: production primarily for domestic consumption and production primarily for export. The two subsectors, however, are quite different, with the export subsector using 88% of the imported agricultural inputs (Warnken) and being characterized by larger landholdings. This segmentation in production has led to the formation of separate subsectoral economic policies.

The principal crops of the Nicaraguan agricultural subsector are export crops—cotton, coffee, tobacco, sesame, and sugarcane; and domestically consumed crops—rice, corn, beans, and sorghum. Cotton, sugarcane, and rice are processed before sale, yielding ginned cotton and cottonseed, sugar, and milled rice. Bananas, although important, will not be treated in this analysis because of a lack of data. Crop production, acreage, domestic price, domestic consumption, export price, and export quantity for 1971 are presented in table 1. In some cases, these data reveal a gap between domestic and export price. Sugar and coffee are traded under a system of international quotas. The other crops are exported through an informal system of quotas (Cappi et al.).

Method

This analysis is carried out with a multicommodity agricultural sector model that explicitly includes the factor markets. This model is designed to simulate a competitive agricultural sector and to reflect the product

Table 1. 1971 Nicaraguan Production Statistics

[e] A commodity after processing.

and factor market impacts of trade distortions. The model is a quadratic programming model of the type introduced by Takayama and Judge and discussed in the recent review paper by McCarl and Spreen.

The model simulates activity within the Nicaraguan agricultural sector involving production, processing, export, import and domestic consumption of sesame, corn, beans, cotton, rice, coffee, sorghum, tobacco rubio, tobacco habano, and sugarcane. Other commodities are treated as exogenous. Operationally, the model maximizes the area between the supply and demand curves subject to supply-demand balance, foreign trade, and resource constraints.

The objective function consists of the area under the domestic demand curve plus export revenue minus the costs of imports, miscellaneous production, credit, chemicals, and processing. The areas under the land and labor supply curves are also subtracted. Constraints are present which balance (*a*) total land use with land supplied, (*b*) labor use with labor supply (from both family and hired sources), (*c*) credit use with credit supply, (*d*) chemical use with chemical supply, and (*e*) product use with product supply. Constraints are also present which limit processing capacity and impose export-import quotas. Fajardo provides details on model specification (the authors also will provide a detailed specification upon request).

Assumptions and Empirical Specification

Several key assumptions are made relative to the sector. First, labor is assumed to be in infinitely elastic supply up to a point, 20% more than current use. It then follows a linear supply curve from that point on, with point elasticity 2. This practice is followed because of the high degree (30%) of rural unemployment (Warnken) and because of a lack of data to utilize other possible assumptions. Second, production of each crop is modeled with only one production activity. Third, it is assumed that the supply curve of land is upward sloping, reflecting a progressively higher cost of either drawing land out of other enterprises (exogenous to the model) or developing additional land. Fourth, credit is modeled with a differential interest rate for each crop, reflecting current conditions in the Nicaraguan sector. Fifth, all other inputs are modeled as infinitely available at a price. These assumptions will not be discussed at great length here and are made on the basis of data availability and knowledge of the sector. (See Fajardo for a thorough discussion of these assumptions.) The way these assumptions are implemented is presented below.

Empirical specification of the model is accomplished using the approach of Miller and Millar. Rather than being built up from micro data, the model is constructed using national average farm budget data (Warnken). The model is empirically forced to reproduce the observed 1971 data, assuming that the sector was in equilibrium during that year. This is similar to the approach that is often used in input-output analysis. The production and processing budgets are normalized on land area or processing level. Use of each input explicitly accounted for in the model (land, labor, credit, fertilizer, and pesticides) is then priced at its 1971 observed price, as is production of each output. The miscellaneous cost item in each budget is then set at the difference between the budget's total cost and total revenue. As a result, at prevailing 1971 prices, marginal revenue and marginal costs of any given activity are equal. This is the condition of optimality for the QP model.

Completion of the model also requires specification of commodity demand, land supply, and hired labor supply schedules. Demand for each commodity is assumed to be represented via a negatively sloped function. Price elasticities are obtained either by manipulating income elasticities (via Frisch's method) or from related work in Mexico (Duloy and Norton). Cross-price elasticities are not included. The linear demand curve formed for each commodity has a prespecified elasticity at the point given by the base-period price and quantity. With respect to foreign trade, Nicaragua is assumed to be a small country facing infinitely elastic (fixed-price) world market supply and demand schedules for all products. Export and import prices are fixed at their 1971 levels, as seen in table 1. Quantitative export and import restrictions are either set at their 1971 levels (as in table 1) or are not effective restrictions.

The land supply is specified in a similar manner. By inspection of the ranges of annual land costs in Warnken, a price of 100 cordobas per manzana is chosen as the base land price. The base quantity of land is the total acreage of crops planted in 1971. A land supply elastic-

ity of +0.2 is chosen, based upon the authors' judgment. A linear land supply curve is therefore included with an elasticity of 0.2 at the 1971 price-quantity point. Credit cost (which varied by crop) is drawn from Central Bank of Nicaragua statistics. Labor cost is set at the national average agricultural wage rate. Fertilizer and pesticide costs are held at 1971 average cost.

Model Verification

The data used in the model specification were from 1971. Thus, the task became to reproduct 1971 economic performance. The model specified above was run without trade restrictions and showed quite a large gap between the actual and predicted outcomes. This difference principally arose in the foreign sector where exports were considerably larger than the observed levels. Domestic consumption was lower than observed. This occurred because in the model, with no barriers to trade, domestic and export or import prices are equal for traded goods. This is inconsistent with the observed divergence between domestic and export prices as given in table 1. An examination of the literature (Cappi et al.) and the authors' experience led to the conclusion that exports are traded under formal and informal quotas.[1] Thus, quantity limits on exports and imports were imposed at 1971 levels and the model was rerun. These results are presented in table 2. Comparing table 2 with table 1, extremely close correspondence was obtained between the trade restricted model and 1971 reality, as expected (given the model specification approach). This model, judged to reproduce adequately 1971, is adopted for further analysis of changes under specified conditions.[2]

Experiments and Results

Perhaps the most interesting question to be answered is what would happen if Nicaragua's agricultural sector were opened to unrestricted foreign trade. This analysis is presented below, as are other analyses on export taxation and import pricing options.

[1] Two alternative hypotheses also can be advanced. First, the model may be misspecified, and the difference between domestic and foreign prices should be considered a marketing margin. Second exporters may be risk-averse; and, thus, risk attitude would explain the difference. The first hypothesis was believed false. The second hypothesis was tested using a Hazell and Scandizzo-type risk model; however, the results were not significantly better and, therefore, are not discussed here.

[2] This procedure does not test the validity of the model for the analysis of changes from the equilibrium. Rather, the model is assumed valid by construction.

Table 2. Base Model Production Results

Commodity	Land[c]	Production[d]	Domestic Consumption[d]	Domestic Price[e]	Exports[d]	Imports[d]
Coffee	150	928.7	224	247.9	704	0

[d] In thousands of hundredweight.
[e] In cordobas per hundredweight.
[f] Both imports and exports are present for these commodities because of the quota structure.

Trade Restriction

Uncertainty in world prices is often cited as a major reason LDCs restrict, or want to impose restrictions on, trade. Quantitative restrictions on trade can aid in stabilizing domestic prices as they cut the link between domestic and world market prices. The model is used to analyze the consequences of restricted versus unrestricted trade under export price uncertainty in an attempt to estimate the magnitude of the dislocation arising from the imposition of quotas. Time-series data obtained on export prices for the three principal export crops—sugar, cotton, and coffee—for the years 1967–74 are given in table 3.

The comparison between unrestricted and restricted trade is made by first running the model with world market prices for each of the eight sample years with trade volumes restricted at 1971 levels and then running through each sample year with unrestricted trade. (Under these cases, the processing restraints were removed.) The results of this analysis are summarized in table 4.

In interpreting these results, several factors need to be considered. First, this is an equilibrium model, which fully adjusts to any shock within one year. Thus, the results do not take into account the perennial nature of some of the crops and other short-run resource fixities. Therefore, it overstates short-run resource adjustments among crops. Further, the formulation assumes that farmers react as if they had perfect knowledge of these prices and seek to maximize net income. The model is rather simple and does not capture risk-averse behavior, many constraints which may dampen adjustment, multiple activities for production of a crop, substitution in demand, or the effect on demand of income change—nor are the terms of trade adjustments captured which potentially would occur with large changes in the balance of trade. Consequently, the model can be said to give a maximum measure of the effects of international price stability (when tested under free trade). Nevertheless, the distributional effects of the price uncertainty are of interest.

The trade restrictions lower the average value of exports, depress rural employment, land prices, consumer prices, and producer prices (table 4). However, under restricted trade, all of these items were more stable, as expected.[3] The domestic consumer paid lower prices (as evidenced by the Laspeyres price index) and faced more stable prices. The producers of exported goods lost, as evidenced by their producer surplus.[4] Thus, the policy of export restrictions transfers income to consumers and producers of domestically consumed goods from export producers.[5]

Export Tax

One means implemented by the Nicaraguan government to obtain tax revenue after the

[3] Table 4 also illustrates one of the benefits of the multicommodity simultaneous trade-policy analysis. Land area is reallocated among crops in response to the policy change consistent with the opportunity costs of producing each crop.

[4] Consumer and producer surplus are used here individually and as a measure of welfare. These topics are somewhat controversial; also the zero cross elasticities cloud the use of this measure. However, the authors felt that in this context these measures were useful. Willig provides discussion and references.

[5] As Jabara and Thompson demonstrate, under risk aversion the subjective cost associated with international price uncertainty may exceed the static welfare losses identified here. But this is beyond the scope of the study.

1972 earthquake was the establishment of an ad valorem tax for export crops. The theory of commercial policy predicts that an export tax on a small (price-taking) country's exports will affect the market for a given good in one of two ways. Either (*a*) the volume of goods exported will fall as will the domestic price; or (*b*) if there is a binding export quota, it merely transfers income (rent) from exporters to the government (as tax revenues) with no changes in production of the good.

A 15% ad valorem export tax is imposed on exports of coffee, sugar, tobacco habano, cotton, and sesame. The solution is summarized under "Export Tax" in table 5. One of the most interesting findings is an observed reduction in the exports of only cotton and sugar. The tax equivalent of the existing export quotas on other crops already was causing more than a 15% difference between their domestic and export prices. Thus, case (*b*) above applied to these crops. In the new equilibrium under the taxes, less coffee was exported, and there were no sugar exports. The area of land planted to coffee fell slightly, and sugarcane land was almost halved. This led to a decrease in land value and a slight increase in the production of other crops. Total land use fell by 13%. Social welfare, measured by consumer plus producer surplus, fell 2.6%. A Laspeyres index of consumers' prices shows a 3.1% reduction, whereas an

index of producers prices shows a 10.9% reduction. Consumers are slightly better off. Labor use fell by 10%. Government revenue from the tax was 74.7 million cordobas. This policy again benefits consumers and domestic producers while discriminating against exporters and reducing rural employment.

Imported Input Subsidies

The prices of imported inputs rose substantially in 1973. As a result, many LDCs subsidized the use of imported inputs. The effects of such a policy are simulated through the imposition of subsidy policies directed toward the chemical inputs.

Three subsidy policies are tested. The specific policies are (*a*) a 20% price subsidy on chemical inputs used for all crops, (*b*) a 20% price subsidy on chemical inputs used for only the domestically consumed crops, and (*c*) a 20% subsidy for domestically consumed crops coupled with a 15% export tax on the crops as above. The results from these three policies are summarized in table 5.

All of the subsidy policies resulted in gains for consumers. Producers gained under the all-crop subsidy policy, came out even under the domestic crop subsidy, and lost under the subsidy-tax policy. In all three cases the net change in government expenditures almost exactly equaled the gain in welfare. Government expenditures were 38.5 million cordobas under the first plan and 5.1 million under the second plan. Under the tax and subsidy program, net government receipts were 74 million cordobas.

Concluding Comments

This paper illustrates the use of a simplified multicommodity modeling approach that readily permits the analyst to conduct trade policy analysis taking into account important simultaneities often ignored in single-commodity analysis. The Nicaraguan crop sector is examined under selected changes in its trade and agricultural policies. The analysis uses a market-oriented, quadratic programming model of the crops sector. The model, constructed to reproduce 1971 conditions, is then used to test sensitivity of the sector to trade liberalization, unstable markets, export taxes, and imported input subsidies.

With regard to the Nicaraguan situation, several observations can be made. First, the production of export crops appears to be profitable, given the quotas in existence. Evidence for this appears in the form of the domestic-international trade differential. Trade in these commodities has been reduced through a system of quotas. Further, at times export taxes have been imposed, affecting export profitability while adding to government tax revenues. The analysis above shows that the net impact across all commodities of such policies is to bring about benefits to consumers and producers of domestically consumed crops, and losses to producers of crops that are primarily exported. Unrestricted trade increases rural employment, but also opens the country to considerably more variability in internal prices and incomes. Input subsidization policies also were examined, and the possibility was demonstrated that the revenues of an export tax might be used in subsidized domestic production.

Above and beyond concerns relating to the Nicaraguan context, this study raises a number of research questions. First, the model used is potentially powerful. The alternative to this model is a larger, more data-intensive model, such as CHAC (Duloy and Norton). The time required to implement the model in this paper can be much less; however, the accuracy of the larger model could (and should) be greater. The research questions that arise, then, are: How accurate is the type of approach used herein? Is this approach inappropriate? When should it not be used? Is the marginal gain from having a more detailed model in fact worth its cost? In many cases the authors feel the above methodology is appropriate for quick, insightful analyses.

The second set of research questions relates to trade or other policy analysis using a multiple-commodity model. The authors feel that in this situation the multicommodity model is appropriate and in fact could build a case for expanding the model scope to nonagricultural and/or monetary sector activity. The appropriate questions then are: Under what conditions is single-commodity analysis appropriate? What are the relative strengths and weaknesses of a single- versus a multiple-commodity model? Finally, how do you know when to stop a model in terms of its scope? This question is important in a country such as Nicaragua, where time, skilled manpower, computer facilities, and quantitative expertise are potential major constraints.

A third set of research questions relates to the use of this model in a stability situation. The model basically assumes equilibrium. Stability analyses are done most frequently with dynamic disequilibrium models. The authors feel each has its place and believe the appropriate question is, when are the results of an equilibrium model appropriate for a stability examination (especially when the model may be put together rather simplistically)? Restrictive assumptions (as above) are certainly necessary.

Effects of Exchange Rate Changes on U.S. Agriculture: A Dynamic Analysis

Robert G. Chambers and Richard E. Just

An econometric model of the wheat, corn, and soybean markets is used to examine the dynamic effects of exchange rate fluctuation on U S. commodity markets. Exports and agricultural prices are found to be sensitive to movements in the exchange rate, while domestic factors, such as disappearance and inventories, are less sensitive but still responsive. Dramatic short-run adjustments in prices and exports are followed by less dramatic but significant longer-run adjustments. Thus, the hypothesis of elastic response to the exchange rate seems particularly relevant for the short run.

Key words: agricultural prices, agricultural trade, exchange rate.

One of the most dramatic events in the international arena over the last decade was the devaluation of the dollar by almost 10% *vis-à-vis* special drawing rights (SDRs) in 1971. The devaluation was largely the result of an increasingly poor international payments situation for the United States. Dramatic as it was, however, the initial devaluation of the dollar was followed by yet another devaluation and eventual floating of the dollar in 1973. During this same period, the United States experienced the first in a series of deficits in the trade account. These facts, coupled with the still weak position of the dollar in international currency markets, have led many trade theoreticians and empiricists to question the overall effectiveness of devaluation as a policy tool. In fact, there is a school of thought (often identified as monetarist) which suggests that devaluation can have only monetary effects, in which case a devaluation likely causes portfolio adjustment but is unlikely to affect seriously the trade balance. Examples of theoretical research on this topic include the series of papers by Laffer (1969, 1976), while the paper by Miles presents some empirical evidence in support of the monetarist hypothesis.

On the other hand, a good deal of attention has been directed at the effect of these devaluations on the agricultural sector of the economy. If a devaluation strongly affects the agricultural sector, then the majority of the associated impact effect must come through an adjustment in the agricultural trade balance rather than through a portfolio adjustment. In an award-winning paper, Schuh has demonstrated (given implicitly nonmonetarist assumptions) that overvaluation and, hence, devaluation could have important effects on both the foreign component as well as the domestic component of the agricultural sector. This latter point is particularly relevant because many of the empirical studies of the effect of a devaluation on U.S. agriculture have concentrated on price and export effects. In a market where production occurs only once a year, however, any factor that impacts on both price and exports will, with little doubt, have important dynamic effects on domestic disappearance and inventory accumulation. One goal of the present study is to investigate the dynamics of these effects in an empirical model. Most of the modeling efforts that have been directed at this problem thus far, either econometric or judgmental, have been static in nature and are thus incapable of portraying the dynamic adjustment to a devaluation. This paper, on the other hand, seeks to identify the

major dynamic characteristics of this adjustment process via dynamic multiplier analysis.

This paper is based on another paper by Chambers and Just which argues that past modeling efforts may have been overly restrictive in their specification of the exchange rate variable in empirical agricultural trade models. Specifically, many cross-price effects which are ignored in applied modeling because of problems of multicollinearity and degrees of freedom, collectively can cause a significant exchange rate effect which might be underestimated (overestimated) by only deflating own price by the exchange rate in an export equation. On the basis of the classic work by Orcutt on international price elasticities under a system of fixed or relatively fixed exchange rates, such as the crawling peg arrangements of Bretton Woods, economic agents also may respond differently to exchange rate adjustments than they do to market price movements. For both of these reasons, reduced-form exchange rate elasticities of price need not be restricted to lie between zero and −1, (0, −1). Because this proposition is clearly testable, some attention is directed at the associated empirical investigation. On balance, the reported statistical results tend to favor the proposition.

In this paper the authors attempt to develop a model which considers exchange rate adjustment as a monetary effect with adequate flexibility in specification, which reflects exchange rate effects on the domestic sector as well as the foreign sector of U.S. agriculture, and which appropriately considers the dynamics of the associated adjustment process. The model concentrates on the markets for the three most important U.S. agricultural exports—wheat, corn, and soybeans. In the following section, a dynamic econometric model of these three markets is presented and discussed. The model is then used to generate dynamic and long-run multipliers to investigate the time path of adjustment to fluctuations in the exchange rate and to a devaluation of the same size as the original devaluation of the Nixon era (in terms of the SDR-dollar rate). By and large, the results indicate that the devaluations of the early 1970s had extremely important effects on agricultural exports and prices as well as on domestic disappearance and inventory accumulation. Interestingly, however, the short-run effects are more dramatic that the long-run effects. The results also suggest that monetary factors in general, such as money supply controls, can have significant effects on agriculture through the exchange rate.

The Structural Model

The econometric model consists of fifteen equations, three of which are identities. These equations explain disappearance, inventories, exports, and production for three commodities—corn, wheat, and soybeans. The model is formulated in a seemingly recursive form with a separate block for each commodity. However, because of the likelihood of cross-block correlation of disturbances, the model is estimated as a single system by three-stage least squares (3SLS) using quarterly data for the period 1969(I)–77(II).

The results of the structural estimation with variable definitions and data sources are presented in table 1. Each functional relationship is assumed to be linear in parameters to simplify the estimation and subsequent dynamic analysis of the model, and each quarterly equation contains indicator variables to account for purely seasonal effects. Also, each equation is estimated in per capita form so as to preserve the linearity of the system and to allow the straightforward induction of a linear (in parameters) reduced-form from the structural estimates.[1] The model as a whole appears to fit well and achieve a sound level of statistical significance, as evidenced by the associated root-mean-squared errors (RMSE) and standard deviations for the estimated parameters (reported in parentheses). The signs of all coefficients appear to be reasonable in terms of a priori expectations.

The estimated model is substantially more aggregated than many models of agricultural markets although much less aggregated than those presented by Clark or Egbert. For example, it is not unusual to separate domestic disappearance of wheat into food disappearance and feed disappearance (e.g., Mo).

[1] This specification has a somewhat peculiar implication that the U.S. population elasticity of total exports is 1. However, population varies little during the sample period used here and is held constant for purposes of examining dynamic adjustments to exchange rate changes below. On the other hand, if exports are not considered in per capita terms while other demands are, then the system including identities becomes nonlinear. Thus, the dynamic analysis (which is the major focus of this paper) becomes messy and, in fact, cannot be performed generally without relying on approximations which may be poor, given the magnitude of changes considered.

Note: Numbers in parentheses are standard errors; numbers in brackets are elasticities. Also, note that *RMSE* denotes root mean squared error and *PRMSE* is *RMSE* divided by the mean of the dependent variable. Variable definitions are as follows:

Jointly Dependent Variables

PWD—per capita wheat disappearance (bushels per person).
PCD—per capita corn disappearance (bushels per person).
PSD—per capita soybean disappearance (bushels per person).
PWI—per capita wheat inventories (bushels per person).
PCI—per capita corn inventories (bushels per person).
PSI—per capita soybean inventories (bushels per person).

Table 1. Continued

PWX—per capita wheat exports (bushels per person).
PCX—per capita corn exports (bushels per person).
PSX—per capita soybean exports (bushels per person).
RPW—wheat price (No. 2 SRW at Chicago) divided by wholesale price index.
RPC—corn price (No. 3 yellow at Chicago) divided by wholesale price index.
RPS—soybean price (No. 1 yellow at Chicago) divided by wholesale price index.
PWPR—per capita wheat production (bushels per person).
PCPR—per capita corn production (bushels per person).
PSPR—per capita soybean production (bushels per person).

Predetermined Variables

SDR—exchange rate (*SDR* per dollar).
RPDI—per capita disposable income divided by wholesale price index.
FALL,
WINT,
SUM—seasonal indicator variables.
CATTLE—number of cattle on feed (million head).
HOG—number of pigs on feed (million head).
PCAT—price of beef cattle, farm level (dollars per cwt.).
THPW—threshold price of wheat (units of account per metric ton).
WSTOCKW—stocks of wheat in other major exporters (metric tons).
PL480—P. L. 480 shipments of wheat (million bushels).
WSTOCKC—stocks of corn in other major exporters (metric tons).
NONUSS—non-U.S. exports of soybeans (metric tons).
RWAP—average price of wheat divided by wholesale price index.
RCAP—average price of corn divided by wholesale price index.
RSAP—average price of soybeans divided by wholesale price index.
RWSP—support price wheat divided by wholesale price index.
RCSP—support price corn divided by wholesale price index.
RSSP—support price soybeans divided by wholesale price index.

In the context of these definitions, *L* indicates a lagged variable, e.g., *PWDL* is lagged per capita demand for wheat.

Also, several empirical studies on U.S. grain exports—for instance, Fletcher, Just, and Schmitz; and Johnson, Grennes, and Thursby—differentiate U.S. exports by country of destination. Mo, for example, further chooses to partition inventories into government-held inventories and privately held inventories. The aggregate nature of the present study, however, is justified by the fact that interest is centered on the net effects of exchange rate fluctuation in each of the markets rather than on each particular component of the market.

Per capita wheat disappearance (*PWD*) is assumed to be a function of the own-price of wheat deflated by the wholesale price index (*RPW*), real per capita disposable income (*RPDI*), the lagged dependent variable, and quarterly indicator variables (*FALL*, *WINT*, *SUM*). The estimated coefficients for *RPW* and *RPDI* are both theoretically plausible and significant in a 5%, one-sided asymptotic sense. The coefficients of each of the indicator variables are all statistically significant, suggesting a strong seasonal effect. The estimated elasticities indicate a fairly inelastic response to the deflated price of wheat (−.087 at means), while wheat appears to be a superior good with an estimated elasticity of deflated income of approximately 1.5.

The per capita corn disappearance (*PCD*) and per capita soybean disappearance (*PSD*) equations are taken to be functions of the own-deflated prices (*RPC* and *RPS*, respectively), and the quarterly indicators. In addition, since corn finds relatively more use for feed, particularly for hogs, domestic corn demand is taken to be a function of the number of hogs on feed (*HOG*), and the price of cattle (*PCAT*), the latter of which reflects short-run adjustments in the livestock industry.[2] Arzac and Wilkinson (p. 301) report a positive income coefficient in their domestic corn demand equation, while the results in table 1 indicate a negative income elasticity for both *PCD* and *PSD*. It should be noted, however, that neither their reported coefficient nor the ones in table 1 are significantly different from zero, and thus, there appears to be little statistical reason to prefer one to the other. Furthermore, a negative income coefficient for a feed grain is not entirely implausible because derived demand due to meat consumption is reflected through the livestock variable. The numbers of cattle and hogs on feed appear to be important in the determination of per capita corn disappearance with elasticities of approximately .5 and .7, respectively. Like Arzac and Wilkinson, table 1 suggests a negative, but statistically insignificant, own-price elasticity for *PCD*.

The estimated inventory equations are based on the hypothesis that inventories are inversely related to own-price and are consistent with the partial adjustment inventory model suggested by Labys (pp. 70–71). Logically, as the own-price rises, the opportunity cost of carrying grain out of a given period rises and the incentives for profit taking increase. The converse is true as price falls. Per capita wheat inventories (*PWI*), thus, are taken to be a function of deflated price, the lagged dependent variable, and the quarterly indicator variables. Own-deflated price has the expected sign and is significant statistically. Per capita corn and soybean inventories (*PCI*, *PSI*) were both estimated as a linear function of own-deflated price, lagged production indicator, the lagged dependent variables, and the quarterly indicator variables. Both equations achieve a strong level of statistical significance. Also, with the exception of soybeans, inventories appear to be responsive to own-price movements although in an inelastic sense. Respective price elasticities are −.247, −.172, and −.033.

As mentioned earlier, the export equations represent somewhat of a departure from traditional modeling of grain exports in their treatment of the exchange rate variable (for alternative specifications see, for example, Johnson, Grennes, and Thursby; Greenshields). The theoretical basis for this specification has been developed in Chambers and Just, and one purpose of the present study is to investigate empirically the validity of the associated argument. Although Chambers and Just argue for including "indices for 'all other' traded commodities and all nontraded commodities" while weighting "the 'all other' commodity index by the exchange rate" (p. 255), the present study follows the simpler alternative of including the *SDR* term as a separate regressor. This is done because the necessary indices are not available and be-

[2] The reader may note that a number of other variables also were considered in explaining domestic disappearance. For example, because soymeal is an important ingredient in some poultry feeds, poultry numbers were considered in the soybean equation but no plausible coefficient could be obtained suggesting that poultry feed demand is not one of the major determinants of domestic soybean demand.

cause deflating own-price and the commodity index by the exchange rate introduces a significant nonlinearity into the system, making multiplier analysis extremely difficult. The own-price term, however, is deflated by the wholesale price index which places a relatively heavy weight on traded commodities while not ignoring nontraded commodities; thus, cross-price effects of nontraded commodities should be depicted adequately.

Also, one might note that exports to centrally planned economies are considered endogenous to the model specified and estimated here. Some previous studies have treated such exports as exogenous in estimating U.S. export demand. To do so, however, denies that central planning bodies possess economic rationality. Internal prices may be meaningless in a centrally planned economy, but certainly external prices can be important. For example, there is no reason to assume that the Soviet Union might not import a little less grain if the price they must pay is very high rather than very low. While such trade may be interrupted occasionally by political factors such as with the recent Russian grain embargo, there is no reason to rule out rational economic responses on the part of both countries when such political barriers are not effective (as they generally were not during the relevant sample period). In fact, the results of Fletcher, Just, and Schmitz, in which exports to the Soviet Union are investigated in a separate equation, verify that this particular centrally planned economy responds significantly to external price incentives.

If centrally planned economies possibly respond to external price incentives, however, then the associated exports are endogenous in grain trade models and any attempt to treat them as exogenous variables generally will lead to biased and inconsistent estimates. Thus, exports to centrally planned economies, as well as other commercial exports, are necessarily considered as endogenous variables which respond to the usual set of external or international economic variables.

With this in mind, per capita wheat exports (*PWX*) are presumed to be a linear function of own-deflated wheat price (denominated in domestic currency units), the exchange rate (*SDR*), the European Community's threshold price (*THPW*) for wheat imports, the stocks of wheat in other major exporting countries (*WSTOCKW*), P.L. 480 shipments of wheat (*PL480*), the lagged dependent variable, and the indicator variables. Per capita corn exports (*PCX*) are represented as a linear function of own-deflated price, the exchange rate, stocks of corn in the other major exporting nations (*WSTOCKC*), the price of soybeans (to represent relevant substitution possibilities), the lagged dependent variable, and the indicator variables. Finally, per capita soybean exports (*PSX*) were taken to be a function of own-deflated price, the exchange rate, non-United States exports (*NONUSS*) of soybeans, the lagged dependent variable, and the seasonal indicators.[3]

The exchange rate variable is highly significant in the corn export equation and significant at a 6% or 7% level in the soybean export equation (asymptotically). While the significance is less in the wheat export equation, other variables also are less significant presumably due to the large number of other explanatory forces considered. For example, by eliminating *WSTOCKW* from the equation (which has a t-ratio of only $-.81$), the *SDR* t-ratio more than doubles to -2.54, while the coefficient increases by only about 30%. The wide range of alternative explanatory variables is retained in the equation to give other forces the maximum opportunity of explaining the endogenous variables which are so highly correlated with exchange rates.

These results coupled with the earlier findings of Fletcher, Just, and Schmitz, and Meilke and de Gorter provide strong empirical evidence supporting the exchange rate specification used in those papers as well as in the present study. Furthermore, the estimated structural exchange rate elasticities for exports (all larger than unity) indicate that the level of U.S. grain exports has been very sensitive to fluctuation in the exchange rate. Hence, the arguments of Schuh and others appear to be valid, and there seems to be evidence that devaluations and depreciations can lead to significant real adjustments in the agricultural trade balance as well as the portfolio

[3] Attempts also were made to incorporate other indicators of the international demand and supply situation such as the level of freight rates and the threshold price of corn. However, apparent problems of multicollinearity with other included regressors led to poor statistical results. Shipments of corn under P.L. 480 were not included because they have amounted to less than 1% of U.S. corn exports. One might also note that while the *SDR*-exchange rate depends perhaps too heavily on developed country exchange rates for general agricultural trade modeling, it is highly correlated with many of the less developed country exchange rates in this sample period because of the dramatic nature of the U.S. devaluations. Thus, its use seems adequate for present purposes, particularly in view of the cost of constructing an alternative basket rate.

adjustment emphasized by monetarists. On the other hand, the estimated price elasticities for exports range from .17 to .46 which, following the arguments of Chambers and Just, indicates a significant differential effect between exchange rate and own-price movements. This differential may be attributed, among other things, to cross-price demand and supply effects reflected through the exchange rate and a differential response rate on the part of economic agents to exchange rate and price movements. The overall, dynamic impact of the exchange rate on these three markets will be investigated in greater detail below.

Modeling production in a quarterly, simultaneous equation system presents an interesting problem since production usually occurs only once a year. (For an exception to this treatment see Bradford and Kelejian.) The overall production model used in the estimation follows from the work of Cromarty and Houck and Ryan. Production is expressed as a function of the deflated support price (*RWSP, RCSP, RSSP*) and the deflated lagged average price (*RWAP, RCAP, RSAP*) received by the farmer. To handle the periodicity problem, both sides of the production equation are multiplied by an indicator variable taking the value 1 in the period when the bulk of production occurs and zero otherwise. This allows the application of system estimation. Each of the estimated equations appears to be significant. However, because of the specification one must bear in mind that the reported standard errors are misleading in a downward direction.

The Reduced-Form Model

The 3SLS derived, reduced-form estimates for the model are reported in table 2 (elasticities are reported in brackets). Because the model appears to be recursive in nature, the reduced form also was estimated by Zellner's seemingly unrelated regression technique. However, because of the similarity of the results, only the derived 3SLS estimates are reported. The coefficients of the reduced form (impact multipliers) are interesting because they present a more accurate picture of the total effects of predetermined variables than simple elasticities computed from the structural form. In particular, the reduced form provides equations for the jointly dependent prices (*RPW, RPC, RPS*) while also recognizing the effect that the exchange rate has on per capita disappearance and inventories of the three commodities. The reduced form is also used to generate the dynamic multipliers associated with the exogenous variables. Before proceeding to the investigation of the dynamic properties of the model, a closer look at the impact elasticities associated with the exchange rate is worthwhile.

One of the main contentions of the paper by Chambers and Just is that restriction of the exchange rate elasticity of price to the closed interval (0, −1) may be incorrect.[4] The results in table 2 clearly support this proposition since none of the impact elasticities are within the unit interval. The impact effect of a change in the exchange rate on deflated grain prices is thus apparently substantial. To gauge the size of this effect, note that the deflated price of wheat was .01531 in the first quarter of 1971 and .02248 in the first quarter of 1975. In the intervening period the *SDR*/$ rate had fallen from 1 to .8040, so about 70% of the increase in the deflated wheat price can be explained by short-run adjustments to the exchange rate. In dollars and cents, the impact effect of such a change is about $1.73 per bushel, whereas the actual price rose by about $2.10. For the same period, all of the increases in corn- and soybean-deflated prices can be explained by the dollar depreciation.

A similar analysis can be performed for the level of wheat, corn, and soybean exports with the result that the depreciation of the exchange rate over that period is capable of explaining all of the increase in wheat and soybean exports and over 90% of the increase in corn exports. Although the preceding experiment may overstate the exchange rate effect somewhat, it serves to demonstrate the significant effect that exchange rate fluctuations can have in moving from a period of fixed exchange rates to a period of fluctuating rates.

---

[4] One might note that under some stringent assumptions, theory implies that the exchange rate elasticity must lie in the interval (0, −1). For example, theorems 4.D.1 and 4.D.3 of Takayama (p. 392–3) imply that if all goods are net gross substitutes and all income elasticities are positive, then this must be the case. However, the estimated system structure in table 1 obviously admits the possibility of negative income elasticities (see the corn and soybean disappearance equation where income serves as a determinant of direct-human or, at least, nonlivestock consumption). Thus, such a restriction is inappropriate. Moreover, even theorems of this type cannot be applied in restricting the exchange rate elasticity if phenomena such as the Orcutt hypothesis are operative. The latter point is particularly relevant since exchange rates were under direct control for a large part of the sample period under investigation here.

Note: Elasticities are reported in brackets.

Turning to the effect of the exchange rate on the other variables in the system, note first of all that the impact effect on production is nil because of the recursive nature of the production equations. However, the exchange rate does impact on the other jointly dependent variables in the system as evidenced by table 2. In particular, *PWI*, and *PCI* seem to be responsive to changes in the exchange rate. This result is interesting because it suggests that the wheat and corn markets react to rapid increases in the level of their exports by drawing relatively more on inventories while the soybean market appears to curtail domestic consumption relatively more.

As well as providing estimates of the effect of the exchange rate on the jointly dependent variables of the system, the reduced form also allows analysis of the effects of other exogenous variables on the system. For example, it appears that the prices of corn and soybeans are fairly sensitive to fluctuations in the number of cattle placed on farms with elasticities of .74 and .60, respectively, while wheat price is fairly responsive to the level of the threshold price in the European Community, with an elasticity of −.62. This latter result is supportive of the model used by Johnson, Grennes, and Thursby. Corn price is particularly sensitive to hog numbers, with an elasticity of 1.09, and is somewhat responsive to short-run livestock market adjustments, with an elasticity of .40 with respect to cattle price.

Dynamic Characteristics of the Model

To investigate the dynamic nature of the model, it can be written (following Chow) as a matrix difference equation. Before examining the dynamic multipliers, one may be interested in the stability of the model, i.e., the eigenvalues which determine the expected time path of the jointly dependent variables (see Chow or Dhrymes).[5] The model is, indeed, stable, having as a dominant root a real, negative eigenvalue with modulus .8804. Although less than one, the size of this eigenvalue suggests that exogenous shocks to the model will have effects that persist for quite some time. In addition to the dominant eigenvalue, there are six other eigenvalues with negative signs, two of which are also quite large; thus, one can expect rather lengthy adjustment processes following exogenous shocks.

Table 3 reports the dynamic (interim) multipliers associated with the exchange rate for lag periods of one to twelve quarters. These multipliers represent a fairly long and smooth adjustment process once the initial shocks are over. The impact multipliers (reduced form coefficients) associated with the exchange rate indicate strong upward pressure on exports and price as an impact effect of a depreciation. The strong upward push on price leads to a slackening of domestic disappearance and inventory accumulation which in turn tends to reduce the rate of price increase originally caused by the depreciating exchange rate. Nevertheless, prices continue to rise as the tendency to satisfy deferred demand increases and, in the second or third quarter, rising prices begin to choke off and reverse the growth in exports. As time wears on, the effects diminish as the system approaches a new equilibrium point. But as the size of the dominant root would suggest, there are still noticeable effects for all of the jointly dependent variables, even in the twelfth period following devaluation.

Dynamic Effects of the First Nixon Devaluation

At the end of 1971, President Nixon announced an approximate 10% devaluation of the dollar (.0789 *SDR*/\$). Because of the considerable controversy in the literature about the effect of this devaluation on agricultural markets, consider a closer empirical examination of the issue in the context of the dynamic model of this paper. To this end, the impact, cumulative, and long-run (equilibrium) multipliers are computed to determine the (*a*) short-run impact effect of such a change in the exchange rate, (*b*) the maximum cumulative effect, and (*c*) the long-run adjustment to such a devaluation. These results are presented in table 4, where numbers in parentheses indicate the lag period.

As suggested by the reduced form, the impact effect of a 10% depreciation of the exchange rate is substantial. Corn exports rise by over 90 million bushels, wheat exports by about 24 million bushels, and soybean exports

[5] Most general proofs of multimarket stability rely on assumptions of net gross substitutability or positive income elasticities for all goods (see, e.g., Takayama, p. 399–406). Because the estimated model in table 2 contains some negative income elasticities, an *ex post* examination of stability of the model is crucial before proceeding with further analysis.

about 8 million bushels. To compensate for this dramatic upsurge in exports in the short run, domestic demand is curtailed. Hence, wheat disappearance falls by 1.7 million bushels, with the bulk of the adjustment coming through a rapid curtailment of wheat inventories. Also, in the corn market, a substantial amount of the increase in exports is accommodated by a disaccumulation of inventories, while in the soybean market the response is more balanced, with disappearance curtailment accounting for approximately 46% of the export rise and inventory adjustment accounting for the other 54%. The sharp upward pressure on overall demand which is not met immediately by a corresponding increase in total availability, of course, leads to a dramatic increase in prices. In such a situation, where supply is highly inelastic, an equal percentage increase in price is not surprising, and, following the arguments of Chambers and Just, suggests perhaps a more than elastic response. Such appears to be the case in table 4, where all the short-run exchange rate elasticities of prices are larger than unity (negatively). Thus, the impact effect of a devaluation is dramatic.

However, such a dramatic increase in prices leads to increased production in later periods, while further eroding the demand for exports as much of the relative price advantage gained by the devaluation is lost to subsequent inflation of domestic prices—a classic problem associated with devaluation policies. The long-run and cumulative effects reported in table 4 support this argument. The peak effects on exports are reached relatively soon after the devaluation. As inflationary tendencies take over, the system tends to cycle toward the steady-state solution and the effects start to wear off. The approximate 10% devaluation is associated with a maximum decrease of wheat disappearance of about 1 million bushels, corn disappearance decreases by about 17 million bushels, and soybean disappearance falls by about 3 million bushels. In all three markets, the bulk of the response can be attributed to inventory disaccumulation. Inventories tend to be sufficient to weather the devaluation (with substantial price increases) because exports peak and begin to fall rather soon after only two or three quarters. The effect on prices seems to dampen rather quickly as a result.

Perhaps the most important questions when investigating changes in exogenous variables

Table 4. Effect of a 10% Devaluation on the U.S. Agricultural Sector

Variable	Impact Effect	Short-Run Elasticity	Largest Effect of Sustained Devaluation	Long-Run Effect of Sustained Devaluation	Long-Run Elasticity
	(Million bushels)

Note: All figures correspond to the means of data in the sample period. Numbers in parentheses indicate the time horizon in quarters corresponding to the largest effect of sustained devaluation.

relate to the total or long-run effects of such a change after a new equilibrium has been reached. These results are represented by columns (3) and (4) in table 4. Here, the long-run elasticities are particularly important. A 10% devaluation calls forth about a 0.7% long-run change in wheat disappearance and about a 2% change in corn and soybean disappearance. Wheat inventories, on the other hand, fall by about 1.2%, corn inventories by about 1.4% and soybean inventories by less than 0.5%. In percentage terms, therefore, the domestic response in the corn market is much more balanced than in the wheat and corn markets. In the long run, wheat market adjustments tend to entail inventory responses, while soybean market adjustments tend to involve consumption responses.

On the other hand, a sustained devaluation signals dramatic long-run changes in the level of grain exports. Wheat exports eventually respond to a 10% devaluation with a 15% rise, corn exports with a 35% rise, and soybean exports with a 7% rise. The response of domestic price levels to a sustained depreciation is also interesting. Only wheat price responds in an inelastic manner over the long run, while both corn and soybean prices appear to be elastic. Hence, there is further empirical support for the proposition of possible elastic response to exchange rates. Interestingly, the estimated long-run domestic wheat price elasticity implied by the present study is markedly similar to that suggested by the work of Johnson, Grennes, and Thursby. Their results suggest that the effect of a 10% devaluation on domestic wheat price would be about 6.9%, while the result here is approximately 7.9%. Nevertheless, the results here suggest a quite elastic short-term impact on domestic prices; thus, important income, welfare, and allocational effects could be realized as the result of such a devaluation, which might be ignored in a more long-run type of model. Since the Johnson, Grennes, and Thursby model is apparently static, its inherent structure is not designed for and, hence, cannot capture the short-run effects investigated here.

Conclusions and Implications

This paper presents a dynamic, quarterly, econometric model of the U.S. wheat, corn, and soybean markets designed to investigate exchange rate specification and the dynamic effects of exchange rate fluctuations on the domestic and foreign sectors of these three markets. The results indicate that exchange rate fluctuation has had a significant real impact on agricultural markets by altering the volume of exports and the relative split between exports and domestic use of the three commodities. Hence, the results suggested by Miles and Laffer do not appear to be generally true for agricultural markets. Although the estimated model is stable, some interesting cy-

clical forces are clearly operative. The dynamic and long-run adjustment of prices and exports to changes in the exchange rate is particularly interesting. In this context, there appears to be empirical support for the major hypotheses of the Chambers-Just paper, while the results presented are not inconsistent with the results of previous modeling efforts such as that presented by Johnson, Grennes, and Thursby. For example, for wheat the short-run exchange rate elasticity of price is well above 1.00 as suggested by Chambers and Just, while the long-run elasticity of .79 is well below 1.00, as obtained in the static model of Johnson, Grennes, and Thursby. In the case of corn and soybeans, however, both short- and long-run exchange rate elasticities of price are well above 1.00.

A second purpose of this study has been to study the dynamic influence of the exchange rate on the agricultural economy. The results suggest a rather complex and long-term adjustment. Disappearance, inventories, and exports adjust somewhat differently among crops. For example, the soybean domestic demand responds quickly to a devaluation while wheat demand responds very slowly. Similarly, soybean price tends to adjust more quickly, while wheat price adjusts more slowly. For all markets, however, exports increase rapidly and then decline somewhat after several quarters. The continued higher level of exports is then sustained partially by a long-term declining trend in inventories. Comparing among crops, price elasticities of supply and demand apparently explain why soybeans respond to devaluation with a relatively large price increase and smaller export growth, while corn and wheat respond with relatively smaller price increases but larger export impacts.

Because the exchange rate is essentially a monetary variable, these results have other important implications for the agricultural sector. For example, an important implication of this research is that policy tools, such as open market operations, which are usually viewed as having little or no effect on agricultural markets can have significant impacts via the exchange rate. Similarly, fluctuation in other monetary variables also can have important effects on U.S. agriculture.

The results further imply that the devaluations and subsequent floating of the dollar may have had important allocational effects within the U.S. economy. If, as is generally supposed, the devaluation did little to enhance the overall balance of trade situation in the United States, there is no doubt that an increased share in export earnings has accrued to the agricultural sector. Another factor which must be considered with respect to the rest of the economy is that the period of study coincides almost exactly with the appearance of the Organization of Petroleum Exporting Countries (OPEC) cartel and the subsequent quantum jump in energy costs to agriculture and other sectors of the economy. Perhaps the coincidence of this development is responsible for the lack of response of overall U.S. trade balances to devaluation. The significant impacts observed in agricultural exports, however, suggest that the devaluation was, after all, quite effective. For example, one might consider just how much worse the balance of trade situation would have been in view of the OPEC development without the counterbalancing effects of a devaluation on agricultural trade.

If the estimates in this study are a reasonable interpretation of the data, it appears that general trade conditions of the United States have an important influence on the agricultural economy that may not be realized for some time after the relevant policy decisions or terms-of-trade observations. More important, the contrasting response of different crops to general trade and policy developments suggests the importance of tailoring any counterbalancing policies (which may be designed to aid adjustments) to the individual sectors of the agricultural economy with which they are intended to deal.

Major Determinants of Ocean Freight Rates for Grains: An Econometric Analysis

James K. Binkley and Bruce Harrer

Econometric analysis of ocean grain rates suggests that ship size and trade volume are of approximately equal importance with distance in determining rates. Use of large ships reduces at-sea costs and hence the role of distance; but larger ships appear to incur higher port costs, which suggests that efficient port facilities are required for scale economies to be realized. Policies to improve shipping technology and increase trade volume can lead to lower rates, reduce geographic differences among exporters, and thus lead to more competitive markets. This implies that the role of transportation in trade analysis should not be ignored.

Key words: freight rates, grain transportation, international trade, ocean shipping, ports.

International trade in bulk agricultural commodities recently has become more important to the world economy. Yet economists have devoted little attention to international shipping. Transport costs between countries can pose a formidable barrier to trade, similar in effect to tariffs and institutional constraints. Sampson and Yeats found transport costs to be a more significant trade barrier for United Kingdom exports than tariffs; Finger and Yeats come to similar conclusions for U.S. imports.

In addition, ocean transportation changes can affect the domestic grain transport system of major exporters, such as the United States and Canada. Jones argues that many studies have examined the efficiency of domestic grain transportation systems, but little has been done internationally. Transport costs are thought to reflect unalterable geographic factors—primarily distance between traders—and, hence, are not policy relevant. Geraci and Prewo and Finger and Yeats have criticized this viewpoint. Many factors can influence rates, and rates need not be directly proportional to distance. For example, rates on grain from the U.S. East Coast to Rotterdam are about 10% higher than corresponding rates from the U.S. Gulf Coast, even though the distance is significantly less. A further problem is that accurate information on ocean freight rates and/or costs is difficult to obtain (Geraci and Prewo). But without analysis of ocean transport costs, it is difficult to formulate intelligent trade policy, since the effects of tariffs and quotas can be confounded with those due to transportation. This lack also may seriously compromise research in international trade, for differences in transport costs can be one of the primary sources of comparative trading advantages among exporters.

This study empirically examines the major factors accounting for cross-sectional differences in ocean freight rates for grains. The emphasis is on factors causing relative rate differences and not on the level of rates. The analysis separates the effect of at-sea costs and port costs on rate differences, and estimates the effects of major port areas on rates. Thus, the role of unalterable versus controllable factors in determining comparative port advantage is examined.

In the next section, the rationale for the approach, hypotheses, and models used in the analysis is developed. The data are described, followed by the estimation results. In the next section, the authors address the role of port areas and factors that give shipping advan-

tages to some ports. Finally come the conclusions of the study.

Model Formulation

Most ocean grain trade moves in general purpose tramp ships or specialized bulk carriers. Tramp ships travel no regularly scheduled routes, generally being chartered on a single-voyage basis. Specialized bulk carriers are more regular in their routes traveled and often carry grain as a return load for voyages involving coal, cars, or other cargo. The market is divided between shipper-owned and/or time-chartered vessels and single-voyage charters. It is the latter that are of interest here, because voyage rates are determined and reported in this market. Rates are set by shippers and shipping firms who bargain through brokers. On the supply side, many shipping firms participate in this market, providing a variety of ship sizes and types. There are no real restrictions on entry, and grain shipping operates virtually without economic regulations. On the demand side, chartering is dominated by five multinational grain firms and by certain governments (H. P. Drewry, Ltd.). This suggests that rates are unlikely to deviate from costs for long, given the possibility that grain firms may expand their existing vessel ownership.[1]

Therefore, conventional concepts of cost were used to select variables for analyzing rate differences. Two equations (described below) were estimated. Each was of the following general form:

$$RATE = f(DIST, SIZE, TERMS, QUART, FLAG, VOL, PORT),$$

where *RATE* is rate (dollars per long ton);[2] *DIST*, voyage distance (thousands of miles); *SIZE*, shipment size (thousands of tons); *TERMS*, loading and unloading terms (explained below); *FLAG*, registry of ships (U.S. or foreign); *QUART*, quarter in which the shipment occurred; *VOL*, volume of grain trade on route in question, 1972–76 (hundreds of shipments); and *PORT*, origin/destination port area of shipment. This formulation does not include some factors that affect costs, most notably input prices. These are assumed to be sufficiently invariant across routes as to have no perceptible impact on cross-sectional differences.

Various hypotheses concerning the effects of these factors on rates are suggested by previous theoretical and empirical results. Obviously, increasing distance will increase costs and, hence, rates. While the exact nature of this effect is basically an empirical question, the results of Geraci and Prewo suggest that as distance increases, rates increase in a decreasing fashion. It is expected that rates in the last quarter of the year are higher, due to demands put on the shipping industry by harvests in Northern Hemisphere grain-producing areas (O'Loughlin). Ships operating under U.S. registry are known to charge higher rates, due to higher costs brought about by U.S. construction and operation restrictions. These ships depend upon cargo preference laws (e.g., P.L. 480 and Russian shipments) for survival, and essentially operate in markets separate from ships of other countries (Cayemberg).

It is reasonable to expect that as the volume of shipments on a route rises, the average rate charged will decline, because of favorable external effects. A more active trade route will involve ports with more efficient handling facilities, better ship provisioning and maintainence, and perhaps lower probability of long waiting times (Bennathan and Walters). In addition, a busy route is likely to generate more backhaul opportunities and, hence, less empty mileage.

The average size of bulk vessels has been rising recently. Because as size of ship increases, such factors as horsepower and manning requirements increase less than proportionally, use of larger ships presents a means of lowering costs, at least those costs incurred at sea. But there are conflicting views concerning the effect of ship size on port costs. Both Kendall and Janson and Schneerson have claimed that port costs rise with size of ship, and that optimal ship size depends upon the trade-off between at-sea economies and port diseconomies. However, Robinson, using regression on data from the Port of Hong Kong, found that larger ships spend less time in port than do smaller ships. Heaver and Studer examined grain shipment data from Vancouver, British Columbia, and found that larger vessels spend more time in port but have faster loading rates.

[1] Because of the nature of supply in ocean shipping, short-run rates often do not reflect costs. Since the data were indexed on a 1976 basis (described below), annual rate fluctuations were removed. Thus, it is only important that relative rates reflect relative costs differences.

[2] A long ton is 2,240 pounds. Throughout the balance of the discussion, the word "ton" is understood to mean "long ton."

In this study, a special effort is made to examine port costs as they relate to shipment size. An aspect of this involves examining interactions between size of shipment and charter terms, which determine responsibility for loading and/or unloading. There are three types of terms employed in the grain trade: "free in and out," in which the charterer pays both loading and unloading; "free discharge," in which the charterer pays unloading but the shipowner pays loading; and "gross terms," in which the shipowner pays both.[3] Any variations in these charges for different shipment sizes can provide information on the relationship between size of vessel and cargo-handling costs. There are port costs other than loading and unloading, such as ship waiting, movement in and out of the harbor, berth changes, and pilotage. These are reflected in rates; and if there exist port diseconomies and at-sea economies, one would expect the function relating rates charged by large ships to distance to have a larger intercept than the corresponding function for small ships (reflecting higher port costs) but a smaller response to distance (reflecting lower at-sea costs), apart from the effect of charter terms.

In order to examine these hypotheses, two linear models are estimated using ordinary least squares (OLS). The first is a relatively simple form, designed to examine the "average" effect of the variables described above. The second model is more complex, intended to explore issues dealing with economies of scale, port costs, and at-sea costs. The dependent variable in each equation is the rate in dollars per long ton. The independent variables in the first equation are distance and distance squared, shipment size and shipment size squared, volume of trade, and dummy variables for U.S. ship registry, gross terms, free discharge, and quarter in which the shipment occurred. The second equation is a covariance model (Johnston), in which coefficients needed to examine hypotheses dealing with scale economies are permitted to vary across shipment size classes. A set of six shipment size classes is substituted for shipment size and its square. Interaction variables between these and the two shipping term dummy variables are added, and slope shifter variables for the shipment size class variables on distance and distance squared are incorporated. This model also contains a set of port origin and estimation dummy variables, which will be discussed in a subsequent section.

Some words on the research methods used are appropriate. Linear equations (as opposed to a log form) are used to permit the separation of fixed (port) costs and variable (at-sea) costs, since port costs affect rates in an additive rather than a multiplicative fashion. The only real difficulty with the procedure relates to aggregation bias (Theil). The data used are observations on individual grain movements. Given the large number of factors likely to affect rates charged on a given shipment, it is clearly not possible that the variables used in the analysis have homogenous effects across observations. Thus, the results should be interpreted not as estimates of the response of rates on individual shipments but as representative of tendencies existing in ocean grain shipping. Although numerical results are of interest, the primary purpose of the study is to identify the relative role of major factors affecting ocean grain rates.

Data

The data used for the study are published ship charters for all grains and soybeans (Maritime Research). These list information on origin, destination, and tonnage of the shipment, name and flag of registry of the ship, rate, and shipping terms. All 1972–76 charters so published were compiled, yielding 9,356 observations.

Certain data modifications were performed. In order to eliminate the year-to-year variability characteristic of ocean freight rates, an indexing procedure was used to put all data on a 1976 basis. The indexes were constructed by calculating mean rates for all years, and then taking the ratio of the 1976 mean to that for each year. The rates were multiplied by the appropriate index. Different indexes were constructed for the major trading routes, and an overall index was used for others.

Because there are in excess of 1,000 individual origins and/or destination points in the sample, ports were aggregated into 16 origin and 34 destination regions, each with a basing point. The distances used in the analysis were based on these points and were obtained from the Marine Distance and Speed Table (Edward W. Sweetman & Co.).

Because the published charters do not ac-

[3] The obverse of free discharge, in which the charterer pays loading and the shipowner pays unloading (known as "f.o.b. terms") is seldom, if ever, used in grain shipping.

count for all movements, a proxy variable for the number of shipments was constructed. For each exporting country, the total volume of grain exports for the sample period was obtained (FAO). This was compared to total exports from each country represented in the sample.[4] The ratio of the former to the latter was calculated, and then the number of shipments in the sample from each port area was augmented by dividing it by the ratio for the country in question.

Table 1 presents some characteristics of the sample. There is strong evidence of scale economies, because average rates steadily decline as average shipment size increases. Also, loading costs appear to be much smaller than unloading costs (since the difference between gross terms and free-in-and-out far exceeds that between gross terms and free discharge). There is evidence that total handling costs can easily exceed at-sea costs, which supports the criticism made by Jansson and Schneerson of previous work: "Current ship-optimizing models are heavily 'at-sea biased' in spite of the fact that the costs incurred in port are generally of a comparable order or magnitude" (p. 288).

Empirical Results

The estimation results for the two equations are presented in table 2. First we will emphasize the "average" effects of the variables, equation (1). Then various interaction effects among the variables, equation (2), will be discussed.

Distance

As expected, equation (1) results indicate a nonlinear effect of distance. While the coefficient on distance is positive (1.988), the negative coefficient on the square of distance (−.061) implies a declining effect as distance increases. For example, the increment in going from a 3,000- to a 4,000-mile voyage is estimated to be $1.56 per ton. The corresponding increment for 5,000 to 6,000 miles is $1.31. Thus, even relatively large differences in distance between traders may not necessarily generate substantial trading advantages, at least in the typical case.

Shipment Size

From equation (1), the estimated coefficients on shipment size and shipment size squared (−.387 and .004, respectively) suggest the presence of scale economies over a large but not unlimited range. Based on data for free-in-and-out shipments in table 1, the average elasticity of rates with respect to shipment size is −.33. Increasing size by 5,000 tons from the sample mean reduces the per ton rate by 71¢. However, the effect of size on per unit rates becomes positive at approximately 50,000 tons, indicating diseconomies beyond that point. This almost surely cannot reflect rising at-sea costs, since at-sea economies are probably unlimited (Jansson and Schneerson). Thus, this evidence of diseconomies is likely to represent port costs, an issue explored below.

[4] The sample comprised the following percentages of exports by major grain producers for 1972–76: United States, 42%; Canada, 31%; Brazil, 48%; Argentina, 35%; Australia, 16%; South Africa, 41%; France, 3%.

Table 1. Rates, Sizes, Terms, and Distances for Sample Data

Shipment Size	Number of Shipments	Average Rate	Average Shipment Size	Average Distance
(Thousands of Tons)		($)	(Tons)	(Miles)

Shipping Terms

The estimated coefficients on the dummy variables denoting shipping terms indicate that rate differentials attributable to handling costs are substantial but lower than implied by the data in table 1. The coefficient for gross terms suggests that inclusion of loading and unloading in the rate leads to an average increase of about $11 a ton; the corresponding increase for loading is $2. The difference in the regression results relative to a comparison of sample means implies that different shipping terms are quoted under different average circumstances. For example, the average distance for shipments quoted as free discharge is lower than that for the other categories (table 1).

Volume of Trade

In both models, the negative coefficient on the number-of-shipments variable and the level of

statistical significance, particularly in equation (1), suggest external economies in ocean shipping, perhaps of fairly substantial practical significance. The estimated coefficient from equation (1) (−.25) implies that increasing shipments on a route by 100 over a five-year period (e.g., a sustained increase of 20 per year) would tend to be associated with a rate reduction of about 25¢ a ton. This does not mean increasing trade volume (for whatever reason) will automatically lower rates. Part of the effect identified may reflect the presence of efficient port facilities, which are associated with high volume routes. The volume may justify the improved facilities, which in turn lead to lower rates. On the other hand, trade volume itself may generate lower rates through increasing the availability of backhauls. Relevant to this, estimation of the second equation (which suggests that volume is of lesser importance than does the first) with no destination variables but with port origin variables yielded a coefficient virtually identical to that in equation (1). The decline in magnitude with the addition of port destination variables implies that part of the volume effect reflects backhaul availability at destinations. Again, however, it could be reflecting the presence of efficient off-loading facilities. It is difficult to determine whether the negative correlation between rates and volume is direct or due to joint correlation with other factors. Undoubtedly both effects are present.

Other Factors

For both models, the magnitude of the coefficient denoting U.S. flag vessel ($10–$11/ton), coupled with its extremely high level of statistical significance, certainly supports the viewpoint that U.S. and foreign flag vessels operate in different markets.[5] This has important implications for any policy designed to expand cargo preference laws for U.S. shipping, as occasionally has been proposed. The estimated coefficients on the seasonal variables indicate that rates in the last quarter of the year are highest. The lowest rate occurs in the first quarter, perhaps caused by the closing of several important port areas during the winter months, temporarily increasing the supply of ships for other port areas, and from seasonal drops in export demand.

Interaction Effects

As stated above, in equation (2) shipment size dummy variables are used in lieu of a continuous variable, with interactions between these and other variables. The size classes are the same as those in table 1, necessitating five dummy variables, with the smallest size class being the "omitted" class from the dummy set. Hence, coefficients on variables involving these classes measure differences as compared to the smallest class.

The estimated coefficients for interaction variables between shipment size and terms display opposing tendencies. For gross terms, they exhibit a downward trend in the premium charged for loading and unloading as shipment size increases. The corresponding estimates involving interaction between shipment size and free discharge (which only involves loading) exhibit an opposite trend. These results suggest economies of scale in discharging cargo and diseconomies in loading, which does not accord well with expectations. Grain-loading ports tend to have more specialized facilities than receiving areas (*Cargo Systems*). Thus, if inadequate port facilities inhibit the use of larger ships, larger vessels should incur higher costs for unloading rather than loading. The result is especially puzzling in view of the fact that many charters quoted under gross terms are destined for less developed countries, which are known to have limited facilities (see table 4 below). Evidently, there are specific factors at work that are not represented in the data, such as a tendency for free discharge to be specified for shipments arising from ports with limited facilities. This cannot be examined because published charters rarely state the exact port of origin, and port areas have significantly differing facilities (even within a single port).[6]

Given the number of observations involved, it is doubtful that the results with respect to gross terms reflect general tendencies of the

[5] However, estimates made by the Office of Management and Budget and reported in *The American Shipper* are considerably higher. For the period 1972–76, OMB's calculations indicated a per-ton rate subsidy ranging between $13.87 and $33.29, considerably higher than the estimates of $11.00 obtained here. Part of this difference stems from the fact that the present study was confined to bulk shipments; shipments of bagged grain were eliminated. Some P.L. 480 shipments involve bagged grain, and these move at high rates, generally at least twice the magnitude of those for bulk shipments.

[6] Table 4 below indicates a greater tendency for free discharge to be specified from certain ports areas than from others. Thus, the results with respect to free discharge probably do reflect some port specificity and, of more importance, individual facility specificity.

population.[7] The results for free discharge are more credible, although possible aggregation bias suggests they, too, should be interpreted with caution. The indication is that loading costs increase rather sharply with ship size. One would expect this to be less true for ports with superior facilities than for those with limited facilities. Grain-handling terminals specifically designed to accommodate large vessels as well as small do exist, and large ship-loading disadvantages can at least partially be overcome (H. P. Drewry; *Cargo Systems*). The estimation results can be viewed as indicating that the benefits from modernized facilities may be substantial.

The other interaction effect examined was to determine whether the functions relating rates to distance vary across shipment size class. This involved the intercept shifters (variables 13 through 17) and the slope shifters for distance (variables 28 through 32) and distance squared (variables 33 through 37). In general, the estimation results support the diseconomies in port, economies-at-sea hypothesis, but not overwhelmingly. The shipment-size intercept shifters display a vague upward trend, but it is not consistent, and the estimates carry a fairly low level of statistical significance. But the general tendency is for the intercepts (and hence port costs other than cargo handling) to rise with shipment size.

The slope shifter for distance indicates a tendency for the slope coefficient on distance to decline for larger shipment sizes, implying that, as distance increases, rates do not rise as much for large shipments as they do for small. But the slope shifter for the square of distance produces an opposite effect: as shipment size increases, so does the coefficient on distance squared. For the larger shipment size classes, the overall shape of the estimated function relating rates to distance is that of a U. The downward-sloping portion occurs for short distances (few large shipments move short distances) and probably reflects a confounding with port costs, as represented by the intercept. Within the range of typical voyage distances (2,500 to 8,000 miles), the function implies a much smaller rate increase as voyage lengthens than is true of the lower size classes.[8] The portion of the function where, due to the effect of distance squared, the slope is positive and increasing (implying a rise in rates more than proportional to the increase in distance) occurs for high values of distance. This surely does not reflect ship-operating characteristics. A plausible explanation is that longer voyages are usually outside major trading routes, often bound for less developed countries (LDCs), and are thus somewhat atypical. However, there may be some inherent disadvantages to using very large ships on long routes, relating to difficulties of finding backhaul traffic to use vessel capacity efficiently, particularly from LDCs.

Analysis of Port Areas

A producer's competitive position in the world grain trade depends upon its comparative advantage in shipping as well as in production. An obvious component of the former is closeness to markets. This study provides evidence that distance may be of relatively small consequence if large vessels are employed, suggesting that a critical factor in shipping advantage is the nature of port systems at origins and destinations. The type of port facilities available, including channel depths, determine the types of ships that can be handled efficiently. A second factor is the location of ports with respect to major trading routes. The effect of trading volume on rates suggests that ship availability can affect a port area's comparative advantage, and hence a port area along a major trading route may enjoy lower shipping rates than one less favorably located.

In table 3 appear the average shipment size and average rate charged for the sixteen major port origin areas included in the sample data, and for four destination areas: North Central Europe, Japan, LDCs, and the rest of the world.[9] The former two are the only major importing areas for bulk agricultural commodities with highly developed port facilities (*Bulk-Systems International*). LDCs generally are located outside major trade routes and have limited facilities. There are significant ship-

[7] There were only sixteen charters in the largest tonnage class quoted under gross terms, twelve of which were on two routes. The results imply virtually no charge for cargo handling for this size class. This cannot be accepted as a characteristic of the population.

[8] For example, in going from a 3,000- to 5,000-mile voyage, the estimated incremental per ton charge in dollars is (by increasing size class) 2.38, 2.94, 2.38, .47, .30, .27; for an increase from 5,000 to 7,000 miles, it is 5.44, 4.30, 1.99, 1.42, 1.76, 1.49.

[9] The choice of LDCs was based on the criterion of countries with 1978 per capita income of $478 or less (U.S. Department of State). These are basically India, Pakistan, Bangladesh, and most of Africa.

Rest of world	4,934	58	1,640	15.36	19,976	—	—

ment size differences among ports, with a negative association between size and rate. The association is not perfect, of course, due to the complexity of the relation between rates and size and the presence of other differences among port areas that impact on rates. Some of these are included in the regression models above. However, others are not. To account for these, a set of fifteen origin dummy variables and a set of three for destinations are included in equation (2). The regions omitted from these two sets were the U.S. Gulf and the rest of the world, respectively.

The resulting regression coefficients appear in table 3. These indicate that, after allowing for the other factors in the equation, some significant differences in shipping rates from/to port areas remain. The results generally support the hypothesis that rates from port areas near major trading routes (e.g., South Africa, the eastern part of the United States, and Canada) are lower than those from areas less favorably located (e.g., the Great Lakes area, the North Pacific Coast, Australia).

The data in table 3 indicate that LDCs are at a competitive disadvantage in world agricultural trade. The average rate to LDCs is more than twice that to North Central Europe and Japan and substantially above the average to other areas. Much of this is evidently explained by factors in equation (2), for differences in dummy variable coefficients are smaller than differences between sample means. Such factors include a disproportionate use of U.S. ships and charters involving handling costs; also, LDCs are relatively far from producing areas and have low trade volumes. Even though shipment sizes are reasonably large, the distance from exporters and major trading routes evidently negates any advantages from use of large ships, as noted above. The remaining LDC disadvantage (as measured by the dummy variable) probably reflects the costs of inadequate ports. Conversely, the negative coefficients for the Europe and Japan dummy variables suggest some combination of the effect of major trading routes and efficient port facilities.

Using study results, the analysis of shipping advantage can be extended. As an example, shipments to North Central Europe from several port areas active in that trade were examined. Because the Gulf is the major exporting area to Europe, the Gulf region was used as a standard of comparison. The results of the procedure appear in table 4. The first column is the difference between the average sample rate from the origin to Europe and the corresponding rate from the U.S. Gulf (which was $5.82). The U.S. Gulf has a comparative advantage in this trade, with substantially lower rates than South American or Great Lakes

Table 4. Analysis of Rate Differences between Major Origins and North Central Europe, as Compared to U.S. Gulf

		Difference		
Origin Area[a]	Actual	Due to Distance and Shipment Size	Due to Distance	Due to Volume of Trade
Brazil	6.65	3.10	.36	2.35
Argentina	11.20	5.55	1.13	2.28
Canada Great Lakes	11.07	3.08	−.35	2.42
U.S. Great Lakes	10.07	2.55	−.31	1.77
Canada East Coast	−.93	−.60	−.98	2.64
Canada St. Lawrence	.15	−.53	−.88	2.16
U.S. East Coast	.62	.07	−.71	1.88

[a] In the order of origins on the table, the distances are (in nautical miles) 5,446, 6,360, 4,369, 4,444, 2,796, 3,178, 3,636; U.S. Gulf = 4,939. Average shipment sizes were 20,992, 16,189, 15,619, 18,426, 26,203, 38,359, 28,730; U.S. Gulf = 42,887. The number of observations were 147, 126, 75, 322, 20, 140, 284; U.S. Gulf = 923.

origins. Only Eastern Canada has a lower sample rate. The remaining columns were computed from equation (2). For each origin, the percentage of traffic on this route in each of the six shipment size classes was computed. Using the appropriate distances, the rate for each tonnage class between the sets of points was estimated, ignoring all factors other than distance and the intercepts. Based on the percentages, a weighted average rate was computed. The second column is the difference between the weighted rate for each origin and that of the Gulf. It thus estimates the advantage of the Gulf due to its distance from Europe and its shipment size distribution. Column three was computed in the same fashion, except that the shipment size distribution for the Gulf was used for all origins. Since shipment sizes for all origins are equalized, this estimates the role of distance alone in determining advantage. The last column is (negative of) the difference between the estimated rate reduction on each route caused by trade volume and the reduction for the U.S. Gulf. In the table, positive entries denote a comparative advantage for the U.S. Gulf, negative entries a disadvantage.

Based on this procedure, the U.S. Gulf has an advantage due to volume and size. (The conclusion concerning size follows from comparing column 3 to column 2). The trade volume advantage underscores the importance of domestic-export transport inter-relationships, for the Gulf's location with respect to inland transportation (particularly the Mississippi River) gives it a high level of shipping activity. It is only for distance that the Gulf has any comparative disadvantage. Note that, if all origin areas had a shipment size distribution as favorable as the Gulf's, the effect of distance on this trade would not be particularly strong. The maximum differential attributable to distance under this procedure is about $2.00 a ton (Canada East Coast vs. Argentina).

Distance, shipment size, and trade volume do not explain all the differences in the sample rates in column 1. Other factors in the equations also play a role. But many of these also reflect port characteristics, such as adequacy of handling facilities and harbors and location relative to major areas of shipping activity, and are related to distance, shipment size, and trade volume. Although the decomposition of ocean freight rates into identifiable components is quite difficult, the results of this study indicate that distance, shipment size, and trade volume are primarily responsible for rate differentials, and that generally none is dominant.

Implications and Conclusions

The most important implications of this study pertain to the relationship between international shipping and the comparative position of countries in the world grain trade. At present, North American producers dominate this trade, with the U.S. and Canada accounting for over two-thirds of seaborne grain shipments. Much of this developed because of production efficiencies (Johnson). However, these countries have transportation advantages: they are well-located with respect to major markets and have relatively efficient ports, many with a high level of shipping activ-

ity. The continuing growth in trade gives other producers incentive to improve both production methods and export marketing, leading to a more competitive trade environment.

The trend toward improved grain-handling facilities and larger vessels suggests a decline in the role of distance in determining patterns of international trade. The study results show that larger ships lead to lower at-sea transport charges. The measurement of the interaction between ship size and port costs did not yield a clear-cut answer, but the evidence points toward a positive relationship. If this is so, inadequate port facilities will hinder further savings in shipping. This is probably why some major exporters recently have made substantial port investments. Such investments are likely to be the primary source of future cost savings in export grain handling. Port areas that make them will benefit vis-à-vis those that do not.

The results show a negative association between a route's grain trade volume and shipping rates. While this reflects the association between traffic volume and efficient port facilities, such factors as backhaul availabilities and ship maintenance are partly responsible for this finding. These external effects, in the long run, may be the most important source of rate differentials among shipping areas. The volume of seaborne trade depends on many factors outside the discretion of individual traders. However, trade policy can affect trade volume. Countries restricting imports not only reduce backhaul opportunities for ships carrying exports, they may find that reduced trade makes investment in port facilities less attractive.

The importance of shipping density has other implications. Small importers may not be able to generate sufficient trade to benefit from high levels of shipping activity, and their erratic demand may preclude the construction of efficient grain off-loading facilities (*Cargo Systems*). Thus, gains may arise if certain well-developed ports serve as transshipment centers, with small vessels serving as the distribution system, a procedure used in Europe. But institutional and geographic constraints may inhibit its application elsewhere. Thus, LDCs may find themselves at a continuing disadvantage in world trade, worsening problems brought by rising food and fuel prices.

For an exporter with several port areas, such as the United States and Canada, port expansion decisions should include the effects of the density factor. The results imply that expansion should occur in the areas with relatively heavy ship traffic. But optimal port improvement and location depend upon the trade-off between inland and export transportation costs. The efficiency of the U.S. export grain transport system perhaps could be enhanced by a combination of domestic transport changes (such as the introduction of long-haul unit trains to certain ports) and port improvements. But neither change may be justified without the other, and it is difficult to effect such changes without coordinating policy. Knowledge of both domestic and export transportation, such as that provided by this study, will assist in evaluating these tradeoffs.

Finally, the study results indicate that relative transport costs between producers and importers do not necessarily, nor even primarily, reflect unalterable geographic factors, but are more a function of transport and port technology and overall patterns of trade, both of which are policy-relevant. This suggests that the effects of changes in international transport costs on trade is itself worthy of study, and that international trade research which does not consider transportation factors may be based on misconceptions and may generate erroneous conclusions.

Rural Financial Market Performance: Implications of Low Delinquency Rates

Robert C. Vogel

In contrast to most developing countries, nonrepayment of agricultural loans has not been a problem for the Costa Rican banking system. Delinquency rates have in fact been lower for agricultural than nonagricultural loans and lowest on loans to small farmers. This good performance is due largely to efficient techniques developed for gathering information about potential borrowers and incentives for borrowers to repay promptly to maintain access to bank loans which carry interest rates substantially below equilibrium. The pattern of low delinquency rates reflects the structure of low interest rates which causes farmers, especially small farmers, to be rationed most severely.

Key words: agricultural credit, Costa Rica, credit rationing, delinquency rates, interest rates.

Low rates of delinquency and default often have been the primary criterion used to measure the success of agricultural credit programs in developing countries. This widespread concern with good repayment records is amply documented in various volumes of the Agency for International Development's (AID) *Spring Review of Small Farmer Credit* (Gonzalez-Vega). Low default and delinquency rates are said to be particularly praiseworthy because they indicate that lenders are careful in their selection of borrowers and forceful in their collection of loans. Good repayment records also are said to indicate that loans are being allocated to productive activities because enough additional income is being generated to repay the loans.

This paper argues that low default and delinquency rates do not necessarily indicate that an agricultural credit program is performing satisfactorily. This does not mean that good repayment records are not necessary for a successful credit program, but rather that they are not a sufficient condition for success. The overriding concern with loan repayments can be explained, if not justified, by the high delinquency rates which typically have plagued agricultural credit operations in developing countries. In contrast to the widespread repayment problems reported by Bottomley (pp. 282–7), Donald (pp. 137–53), the World Bank (pp. 140–3), and the AID *Spring Review*, low delinquency rates characterize agricultural credit operations in Costa Rica, the case to be examined in this paper. However, these low delinquency rates have been achieved in part at the cost of a perverse selection of borrowers; that is, small farmers who are supposed to be the main beneficiaries of the Costa Rican agricultural credit system are in fact rationed more stringently in their access to credit than other classes of borrowers.

The evidence on delinquency rates in Costa Rica presented in the next section of this paper shows not only that overall delinquency rates are quite low, but also that delinquency rates tend to be lower for agricultural than for nonagricultural loans and lowest on loans to small farmers. This unusual pattern is worthy of detailed analysis, if not emulation. However, the analysis which follows reveals negative as well as positive aspects to this pattern of delinquency rates. The Costa Rican agricultural credit system is worthy of emulation in that it efficiently processes information about the probable repayment performance of potential borrowers and provides incentives that encourage borrowers to repay promptly. One of the main incentives for prompt repayment is

Robert C. Vogel is a professor of economics, Syracuse University, and visiting professor of agricultural economics, Ohio State University.

The author is indebted to Dale Adams, Chris Andrew, Gordon Donald, Jerry Ladman, Donald Larson, Warren Lee, W. W. McPherson, and especially to Claudio Gonzalez-Vega for helpful comments. The generous assistance of numerous Costa Rican bank officials is also greatly appreciated, but none of these individuals is responsible for any remaining errors.

the promise of continued access to credit at interest rates substantially below market equilibrium, but this interest rate structure also provides lenders with an incentive to lend only to those small farmers who are judged to be less risky than potential borrowers in other categories. Moreover, the subsidy implicit in these below-equilibrium interest rates makes it impossible to conclude that good repayment records show that loans are being allocated to productive activities.

Evidence of Low Delinquency Rates

The banking system in Costa Rica consists of a central bank and four commercial banks, all owned by the government of Costa Rica. These four commercial banks are the predominant source of agricultural credit in Costa Rica and provide virtually all of the institutional credit for agriculture (see Vogel and Gonzalez-Vega, especially pp. 10–35, 147). The commercial banks also lend substantial amounts for nonagricultural purposes, but agricultural lending (including both crops and livestock) is the primary component and comprises almost half of the total portfolio (see Banco Central de Costa Rica). The first set of data on delinquency rates to be examined pertains to all four commercial banks and includes nonagricultural as well as agricultural loans. For two commercial banks, more detailed information is available on delinquency rates for agricultural loans, and these latter data provide the basis for most of the main conclusions.

Delinquency rates for the commercial departments of the four banks as of the end of each year 1969–74 are reported in table 1. These delinquency rates are measured by the total value of loans with any payment of interest or principal overdue as a percentage of the total value of loans outstanding. However, some researchers, such as Donald (pp. 138–9), have suggested that delinquency rates might better be calculated on the basis of the value of loans disbursed or falling due during a year. In the case of Costa Rica, such alternative bases for calculating delinquency rates would make little difference. Because of the predominance of short-term loans, the amount falling due each year has averaged over 80% of the amount outstanding at the end of each year, so that delinquency rates calculated on this basis would be only slightly higher than the rates reported. Delinquency rates calculated on the basis of amounts disbursed actually would be slightly lower than the rates reported because of the approximately 20% per year growth in lending.

The data in table 1 initially seem to suggest that delinquent loans may be a problem for Costa Rican commercial banks as approximately one-third of credit outstanding is overdue. However, only 3%–4% have payments more than one year overdue, and the percentage of credit between ninety-one days and one year overdue has declined over the 1969–74 period. Moreover, the high proportion of credit with payments between one and ninety days overdue should not be taken to indicate a serious delinquency problem because it reflects primarily Costa Rican bank policy. Judicial proceedings against delinquent borrowers are not initiated until payments are ninety days overdue; but thereafter, delinquent borrowers are actively pursued. Judicial proceedings may be suspended if an agreement can be reached for reasonably prompt repayment, so that only about half the credit more than ninety days overdue is actually under judicial proceedings.

As stated above, more detailed information on delinquency rates is available for two of the four commercial banks. The first of these is the Banco Nacional de Costa Rica, which is by far the most important as it accounts for almost half of total bank credit and almost 60% of bank agricultural credit. In addition, the

Table 1. Commercial Departments of Costa Rican Commercial Banks: Delinquent Loans as a Percentage of Credit Outstanding at End of Year, 1969–74

Rural Credit Department of the Banco Nacional has long been a pioneer in lending to small farmers and continues to be an important source of agricultural credit (see Gonzalez-Vega).[1] Table 2 reports the delinquency rates at the end of each quarter of 1974 for the Rural Credit Department and the three components of the Banco Nacional's Commercial Department: the central office, the financiera section, and the regional offices. The figures in tables 1 and 2 are mutually supportive in two respects. First, most delinquency rates are reasonably stable during the year and, in particular, year-end delinquency rates do not systematically understate end-of-quarter delinquency rates. Second, year-end delinquency rates for the total Banco Nacional correspond quite closely to 1974 delinquency rates for the four banks combined, which suggests that the patterns observed for the Banco Nacional may accurately describe the other three banks.

The most significant pattern which emerges from table 2 is that delinquency rates are substantially higher for the central office and the financiera section than for the regional offices and the rural credit department. This pattern closely parallels appreciable differences in average loan size and in purposes for which loans are granted (see Banco Nacional de Costa Rica). Less than 10% of the credit from the financiera section and about 60% from the central office is for agriculture, in contrast to more than 80% from the regional offices and 99% from the rural credit department. In addition, average loan size for the central office is more than 300,000 colones, in contrast to approximately 100,000 colones for the regional offices and less than 10,000 colones for the rural credit department (8.57 colones equals one U.S. dollar). Thus, lower delinquency rates appear to be associated with smaller loans and with lending for agricultural purposes.

The other commercial bank for which more detailed information is available on delinquency rates is the Banco Anglo Costarricense. The Banco Anglo is the third largest bank and accounts for almost 15% of bank agricultural credit and more than 15% of total bank credit (see Banco Anglo Costarricense). The detailed information on the Banco Anglo is particularly useful because delinquency rates are reported for different categories of loans and because loans which are on time without extensions or other forms of refinancing are distinguished from those loans for

[1] To qualify as a small farmer under Costa Rican banking regulations, a borrower must have a net income of less than 25,000 colones and total bank loans of less than 100,000 colones, and these same limits apply to all clients of the Banco Nacional's rural credit department.

which extension or refinancing has been granted. The percentage of credit delinquent and with extensions or other forms of refinancing is reported in table 3 for the Banco Anglo as of the end of June 1974.

An important conclusion which emerges from table 3 is that a generous policy of loan extensions and refinancing is not primarily responsible for low delinquency rates in Costa Rica. Just 10% of livestock credit is on time because of extension or refinancing, and even this compares with only 2%–3% for crop and small farmer loans. In addition, delinquency rates for the Banco Anglo confirm the patterns indicated by the data for the Banco Nacional. Among the different categories in table 3, delinquency rates tend to be lowest on crop, livestock, and especially small farmer loans. The percentage of credit between 91 and 360 days overdue and more than 360 days overdue is particularly low for the agricultural categories, especially for small farmers.

The evidence presented above leads unequivocally to the conclusion that delinquent agricultural loans are not a serious problem for Costa Rican commercial banks. In fact, delinquency rates in Costa Rica tend to be lower for agricultural than for nonagricultural loans and to be lowest of all on loans to small farmers. As noted initially, this experience stands in marked contrast to the widespread repayment problems for most agricultural credit operations in developing countries, especially when the lending agency is a government institution.[2]

[2] Delinquency rates on bank agricultural loans in Costa Rica are not appreciably higher than delinquency rates in the United States on loans from Federal Land Banks and Production Credit Associations and appear to be somewhat lower than delinquency rates on loans from the Farmers Home Administration.

Causes of Low Delinquency Rates

Two attributes of the Costa Rican banking system are primarily responsible for the pattern of low delinquency rates achieved. The first is that the Banco Central de Costa Rica establishes the interest rates at which commercial banks can lend, and these interest rates have been set well below the equilibrium levels which would equate demand with supply. From before 1969 through September 1974, interest rates on agricultural loans were set at 8% or 9% (plus commissions of 1%–2% on some loans), while interest rates on various types of nonagricultural loans were set as high as 13% plus commissions. Small farmers are charged the lowest rate, 8%, and pay no commissions.[3] The stated objective of these low interest rates is to promote developmental activities, especially in the agricultural sector, and to benefit disadvantaged borrowers, particularly small farmers. However, the main result of such below-equilibrium interest rates is an excess demand for credit which necessitates some form of rationing.

Excess demand for bank agricultural credit in Costa Rica has been documented thoroughly in a 1969 survey by Vogel and Gonzalez-Vega that includes interviews with more than four hundred farmers and more than fifty bank officials. Those interviewed reported that loan applications were rejected and amounts lent were limited because the

[3] Faced with mounting inflation, the Banco Central raised interest rates somewhat at the end of September 1974. Interest rates on some agricultural loans were set as high as 11% and for some nonagricultural loans as high as 18%, but loans to small farmers remained at 8%. These changes are too late and too small to have influenced the behavior of delinquency rates for the period covered in this paper.

Table 3. Commercial Department of the Banco Anglo Costarricense: Delinquent Loans as a Percentage of Credit Outstanding by Category as of 30 June 1974

	On Time without Extension	On Time with Extension	Total Overdue	1–90 Days Overdue	91–360 Days Overdue	More Than 360 Days Overdue
Crops	85.85	2.30	10.85	6.11	1.28	3.46
Livestock	77.35	10.10	12.55	10.34	1.94	0.27
Small farmer	91.90	3.31	4.79	3.25	1.20	0.34
Industry	74.71	5.20	20.09	9.93	5.84	4.32

demand for credit by qualified borrowers at low bank interest rates substantially exceeded the funds available. Many farmers reported borrowing from nonbank sources at higher interest rates, and even those farmers with bank loans reported using on the average 1.5 nonbank sources of agricultural credit. No comprehensive survey has been carried out since 1969, but the excess demand for bank agricultural credit almost certainly has increased because higher rates of inflation have reduced real interest rates to negative levels in 1973 and 1974. The rate of inflation in Costa Rica remained well below 5% per year through 1969, hovered around 5% from 1970 through 1972, and then accelerated dramatically to 15% in 1973 and well over 20% in 1974.

Promises of continuing access to bank credit at interest rates well below equilibrium can provide borrowers with strong incentives to repay loans promptly. However, as the AID *Spring Review* thoroughly documents, low interest rates on bank agricultural loans are as widespread as repayment problems in developing countries. What distinguishes Costa Rica from the high delinquency rates found elsewhere is the promise of more low interest rate bank credit in the future if repayment is prompt, but not otherwise. Costa Rican farmers are aware not only of the longevity and continuity of the banking system and of the increasing amounts of credit available for agriculture, but also of the sanctions for failing to repay promptly. Even if the only sanction were the refusal of future loans, most Costa Rican farmers would nonetheless repay promptly because the likelihood of a larger low interest rate loan in the future outweighs in most cases the transaction costs of repaying and negotiating a new loan.

The relatively high proportion of loans between one and ninety days overdue provides an important illustration of the trade-off between prompt repayment and delinquency. In spite of the absence of explicit sanctions during the first ninety days, the majority of borrowers nonetheless repay on time and thereby avoid the possible damage to their reputations which might restrict future access to bank loans. Those borrowers who delay repayment for up to ninety days apparently find that the profitability of employing these resources for the additional time outweighs the possible damage to their credit worthiness. The increase after 1970 in loans between one and ninety days overdue (see table 1) may well reflect a change in this delinquency-repayment trade-off associated with increasing inflation in Costa Rica. Higher rates of inflation imply lower real interest rates which, other things being equal, make it more profitable to delay repayment for up to ninety days.

The second attribute responsible for the pattern of low delinquency rates is the internal operation of the Costa Rican commercial banks and, in particular, the incentives which lead bank officials to ration credit in a certain way and the mechanisms which have been developed to obtain information about the probable repayment performance of potential borrowers. It should be noted initially that the long tradition of professional banking in Costa Rica and the high salaries compared to most government and many private-sector institutions make it quite easy for the banks to attract highly qualified personnel. Because the commercial banks are government institutions, these personnel might be more strongly motivated to promote developmental activities and to aid the disadvantaged than to maximize profits. However, nonprofit objectives are given little weight for a variety of reasons. Allocating credit to projects with good repayment prospects, and thereby promoting bank profits, can readily be justified as supporting projects with high returns and hence promoting economic development. The low interest rates established for disadvantaged groups (e.g., small farmers) can be an excuse for not giving additional consideration to these groups in allocating credit.

Profit maximization is the dominant objective, mainly because it directly benefits bank employees. Salary increases are based in part on bank profits, and a portion of profits is channeled into pension funds and other fringe benefits for bank employees. Promotion is influenced in part by the profitability of the office or operation for which an employee is responsible. In addition, profitable banks grow more rapidly, and working for a large and growing bank can provide more power and prestige, as well as a higher salary.

In an attempt to assure some compliance with the objectives of promoting development and aiding the disadvantaged, the Central Bank sets various upper and lower limits on the amount of bank credit for certain activities and groups of borrowers. However, Gonzalez-Vega (pp. 20–30) argues convincingly that these credit limits are not part of any systematic plan, but rather are based largely

on projections of historical trends and are also quite vulnerable to political influence. Because the credit limits are often not binding and bank officials generally have some flexibility in allocating credit, even these limits have come to reflect profit considerations as much as development or welfare objectives.

Various models have been developed to explain bank lending under conditions of profit maximization (see, for example, Jaffee and Modigliani). The Costa Rican case is simpler in most respects because interest rates are fixed, so that bank officials can influence revenues only by varying the amounts lent in each category (within the credit limits). Allocating credit under conditions of excess demand to minimize costs thus becomes the primary focus of the analysis, and costs can be divided conveniently into four components: (*a*) cost of funds, including opportunity costs; (*b*) fixed costs associated with processing each loan; (*c*) costs resulting from delinquency and default; and (*d*) costs incurred attempting to reduce the probability of delinquency and default.

The first two costs can be dealt with quite simply. Although certain categories of activities and borrowers have special lines of credit from the Central Bank or foreign sources, there is no evidence that the cost of funds differs among categories at the margin. The fixed costs of processing a loan will, of course, decline per dollar lent as loan size increases. The last two costs involve a tradeoff, as the risks of delinquency and default can be reduced by obtaining more information about potential borrowers and their prospective projects before loans are made and, afterwards, by pursuing problem borrowers more diligently. Higher costs of obtaining information about a particular category of borrowers imply, other things being equal, less information gathering and hence higher perceived risks of delinquency and default for that category.

The mechanisms developed in Costa Rica to obtain information at low cost about the probable repayment performance of potential borrowers are particularly important because in most developing countries the high cost of obtaining such information has severely limited the access of small farmers to bank credit. The Costa Rican banks are quite decentralized, in that most loans can be approved at local offices by branch managers (who typically are trained in agriculture as well as banking) together with local boards of directors. Each local board is composed of three residents of the area, mostly successful farmers, who are intimately aware of the reputations of potential borrowers for honesty and ability as farmers. This innovative approach to evaluating loan applications (see Gonzalez-Vega, especially pp. 43–48, 96–100) was begun as early as 1914 by the predecessor of the Banco Nacional's rural credit department and, more recently, has been adopted by the other three banks' small farmer credit offices.

Statements made by Costa Rican bank employees during the 1969 agricultural credit survey (and reiterated more recently to the author) indicate clearly the costs of obtaining different kinds of information and the value of this information in reducing the risks of delinquency and default. According to these statements, the main criteria used to evaluate potential borrowers are prior economic success, especially in farming, and a reputation for fulfilling past obligations. Such information can be obtained quickly and cheaply from bank records and from the knowledge of residents who serve on local bank boards. On the other hand, investment plans showing the anticipated returns from projects receive almost no weight in loan approval decisions, even though such investment plans normally are a required part of loan applications. The detailed analysis necessary to make these investment plans useful in projecting returns would be costly and time consuming. Moreover, with low, even negative, real interest rates on bank agricultural loans, most projects proposed by successful farmers are likely to appear profitable, so that prompt repayment can be expected from those farmers who also have good records of fulfilling past obligations.[4]

Guarantees normally are required for bank loans in Costa Rica and might be expected to provide additional assurance of repayment, but bank employees reported that guarantees receive little weight in evaluating loan applications. The reluctance to rely on guarantees

[4] The recognition that credit often may be diverted to uses other than those indicated in the investment plan further reduces the importance of investment plans. Farmers present the projects which they think will be most attractive to bankers, but the credit obtained often is used to finance alternative investments that appear more profitable to farmers. To the extent that alternative investments actually yield higher returns, bankers should not be too displeased because loan repayment prospects are enhanced. Moreover, efforts to prevent credit diversion, such as those criticized by Lipton (especially p. 549), are likely to be both costly and futile.

reflects the costly procedures and political problems that can arise in exercising guarantees to collect overdue loans. The relative costs of exercising different types of guarantees are reflected in the preference of Costa Rican bankers for cosigners and mortgages over cattle rather than mortgages over farms. Cosigners can be as ready as bankers to apply pressure for prompt repayment, while taking away a delinquent borrower's cattle is procedurally and politically far less costly than taking away his farm.

The cost and value of different kinds of information in reducing the risks of delinquency and default not only have resulted in heavy emphasis on prior success in farming and a record of fulfilling past obligations but also have tended to bias the allocation of bank credit away from new crops and new borrowers and toward traditional crops and returning borrowers. Because gathering information about new crops and new borrowers is relatively costly, they are viewed as too risky and consequently receive little bank credit. Traditional crops, on the other hand, are allocated a much larger share of credit than their share of agricultural output would warrant. According to the Ministerio de Agricultura y Ganaderia, just five crops (coffee, rice, sugar, and beef and dairy cattle) accounted for almost 90% of bank agricultural credit disbursed during the 1970–74 period, and coffee and beef cattle alone accounted for about 75%. However, information costs are not necessarily biased against small farmers. Many of them are returning borrowers growing traditional crops, and the innovations discussed above have been particularly effective in reducing the costs of obtaining information about small farmers. Nonetheless, the availability of credit for small farmers, especially if they are new borrowers, should not be overestimated, as the Banco Nacional's rural credit department actually made fewer loans each year in the early 1970s than in the early 1950s (see Gonzalez-Vega, p. 50).

The Costa Rican policy of setting interest rates below equilibrium has been shown to create an excess demand for bank agricultural credit and to necessitate some form of rationing. The structure of these interest rates, together with the foregoing examination of costs, especially information costs, also can explain in the context of profit maximization why Costa Rican bankers have rationed credit to achieve the observed pattern of delinquency rates: lower for agricultural than for nonagricultural loans and lowest on loans to small farmers. For each loan application, bank officials will obtain information about the potential borrower until the cost of this information equals, at the margin, its value in reducing the anticipated risks of delinquency and default. Bank officials can then be viewed as ranking loan applications according to the probability of delinquency and default and allocating available credit by going down the list of potential borrowers from low risk to high risk. If Costa Rican bank officials are competent evaluators, this *ex ante* assessment of risk should be reflected in the delinquency rates achieved *ex post*.

Risks, and hence delinquency rates, will not be equalized for different categories of borrowers to the extent that revenues and costs differ among categories. As indicated above, the Central Bank has set lower interest rates for agricultural loans than for most nonagricultural loans and has reserved the lowest rates for small farmers. Bank officials thus will proceed farther down the list to serve higher-risk applicants in the higher-revenue nonagricultural categories and least far down the list in serving small farmers whose loans produce the lowest revenues. If it is assumed that costs of funds are equal for different categories of borrowers, that fixed costs of processing loans are negligible, and that *ex post* delinquency accurately reflects *ex ante* risks because of efficient information gathering, then interest rates (including commissions) of 8% for small farmers, 10% for other farmers, and 14% for nonagricultural loans imply that nonrepayment rates of 3% for small farmers, 5% for other farmers, and 8% for nonagricultural loans would equalize the expected returns to the bank for the different categories. Such nonrepayment rates would not be inconsistent with the pattern of delinquency rates reported in tables 2 and 3.

Conclusion

The Costa Rican banking system has achieved relatively wide service to the agricultural sector, including small farmers, together with low rates of delinquency and default because of the efficient techniques developed for gathering information about potential borrowers and the profit orientation of bank employees. The system also provides strong incentives for

borrowers to repay promptly, not primarily because of explicit sanctions but rather because of the promise of continuing access to bank credit if repayment is prompt but not otherwise. Continuing access to bank credit is attractive in part because of the below-equilibrium interest rates charged on bank loans. However, below-equilibirum interest rates imply excess demand and hence rationing, and the structure of low interest rates for certain categories of borrowers further implies that these borrowers will be rationed most stringently in their access to bank credit. Such rationing, which tends to offset the benefits for the agricultural sector of innovations in information gathering, is reflected in the pattern of lower delinquency rates for agricultural than for nonagricultural loans with lowest rates on loans to small farmers.

The stated objective of low interest rates on agricultural loans, especially to small farmers, is to promote developmental activities and to benefit disadvantaged borrowers. However, as shown above, these deserving borrowers are in fact more severely limited in access to bank credit than other borrowers. Moreover, low delinquency rates do not provide evidence that bank loans are used to finance productive activities in the agricultural sector. Negative real interest rates, such as existed in Costa Rica for bank agricultural loans in 1973 and 1974, mean that borrowers can undertake projects with negative real rates of return and still generate enough income to repay bank loans. The fungibility of credit, including the limited ability of bankers to control even outright diversion of credit to unprescribed uses, means, furthermore, that agricultural loans may not have financed even unproductive agricultural activities.

If low interest rates in Costa Rica are associated with low rates of delinquency and default, might not a movement to higher interest rates provoke an undesirable increase in delinquency? In part such an increase in delinquency would be desirable as it would reflect incentives for bank officials to lend for riskier projects provided the projects had high expected returns. Higher interest rates also could encourage further innovations in information gathering to evaluate new borrowers and new crops and thereby lessen the concentration of credit in loans to returning borrowers and traditional crops. However, the increase in delinquency would also undoubtedly reflect a reduced incentive for borrowers to repay promptly because maintaining access to bank credit would not be as attractive with higher interest rates. Even this undesirable increase in delinquency might have beneficial aspects if it prompted bank officials to search for other ways to improve service and thereby to increase the attractiveness of bank credit.

The Political Economy of Agricultural Credit: The Case of Bolivia

Jerry R. Ladman and Ronald L. Tinnermeier

A theoretical framework is established to show that agricultural credit programs in less developed countries can be used for political purposes because of (*a*) government-controlled supply; (*b*) implicit income transfers associated with concessionary interest rates, delinquency, and inflation that can be used as patronage for politically influential borrowers; and (*c*) ease of implementation under guise of economic objectives. The framework is applied to Bolivia. Within that country's political context, large income transfers to a few influential farmers strongly suggest the importance of political factors in credit allocation with consequent effects on income distribution, development, and debilitation of financial institutions.

Key words: agricultural credit, Bolivia, income transfers, political economy, subsidies.

Agricultural credit has been a cornerstone of most agricultural development programs in less developed countries (LDCs). Domestic governments and donors of foreign aid alike have allocated significant sums for agricultural credit programs (Adams). This paper argues that, although such programs are said to be economically oriented, they are susceptible to being used by LDC governments as political tools. Thus, a political economy of agricultural credit emerges in which credit is allocated to satisfy political objectives.

There are five major reasons why the political economy of agricultural credit has become important. First, governments typically control the formal market supply of agricultural credit through development banks and credit policies which force private sector lending to agriculture. Therefore, governments have the ability to influence strongly the distribution and allocation of credit. Second, concessionary interest rate policies, which are almost ubiquitous in LDC agricultural credit programs, provide for an attractive income transfer to borrowers. Third, when governments permit long-term delinquency, a common condition in LDCs, the borrower receives a temporary income transfer for the period of the delinquency. If he never repays, it becomes a permanent transfer. Fourth, when inflation is present, the magnitude of the concessionary and delinquency transfers is magnified. Fifth, the advantages of obtaining these transfers are sufficiently attractive that they can be used by governments to gain patronage of borrowers and, conversely, by borrowers to pledge support to government.

Credit programs are particularly alluring for political purposes. First, they are easy to establish and administer. Second, they are legitimate for economic objectives. Third, because monies are fungible and because of the hidden transfers, the true uses of such funds are difficult to identify. Thus, credit lends itself to being used for political purposes under the guise of economic development.

The extent to which economic decisions are influenced by political factors, or vice versa, is difficult to ascertain in practice. It is becoming increasingly clear, however, that not only is there the potential for political forces to impact heavily on agricultural credit programs, but also they probably play a more important role than has been previously recognized (e.g., see Von Pischke).

This paper first describes the evolution of

the institutional and policy structure of credit programs in LDCs. The role of foreign aid is emphasized. Second, a framework for the political economy of agricultural credit is specified. Third, the framework is applied to Bolivia, an archetype of underdevelopment where political factors often predominate and where there have been massive infusions of foreign aid for agricultural credit. Fourth, conclusions and policy implications are set forth.

The Evolution of Institutional and Policy Structures

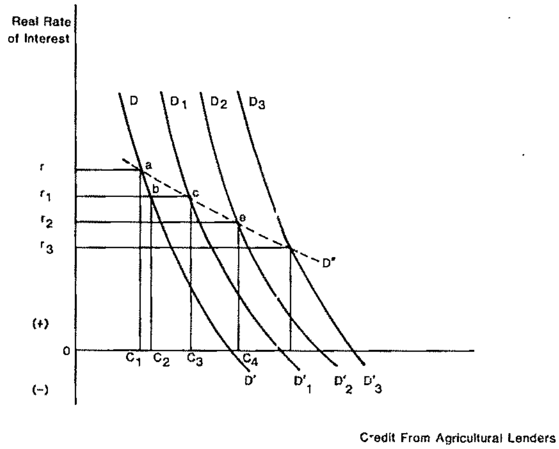
Commercial financial institutions in LDCs have shunned lending to agriculture because of the high costs and risks embodied in these loans (Donald, pp. 27–35). Thus, pressures were placed on government to provide alternative sources of financing. The passivity of the agricultural sector suggested a supply-leading financial approach (Patrick). Government agricultural banks were commonly established. Yet, when it became obvious that government institutions could not meet the needs of financing agriculture, means were sought to force the private sector to lend to agriculture. Central bank rediscount mechanisms, loan guarantees and loan portfolio requirements were common policies.

Almost without exception all of these agricultural credit programs incorporated a feature transferred from the U.S. Farmers Home Administration credit model—the concessionary interest rate; because, from an economic standpoint, it provided elements deemed appropriate to the conditions of LDCs. The concessionary transfer (the income transfer due to the concession) was justified to encourage the use of more highly productive inputs, and to compensate the farmer for the inherent risks in agriculture, the paucity of cost-reducing infrastructure in the countryside, the past injustices done to farmers by moneylenders, and low product prices imposed by the government to protect the interests of urban wage earners (Donald, pp. 101–03). Little attention has been directed heretofore to the tremendous political leverage that the concessionary transfer offers.

A Framework for the Political Economy of Agricultural Credit

Figure 1 presents a country-wide demand curve DD' for credit from agricultural lenders

Figure 1. Demand for credit from agricultural lenders



to be used for agricultural purposes when interest rates are equalized throughout the economy. Assume that the prevailing real interest rate is r; therefore, farmers would want to utilize OC_1 credit. Suppose, however, that the government subsidized agriculture by means of a concessionary interest rate, r_1, for agricultural loans but left interest rates for nonagricultural loans at the previous levels.[1] Two effects would occur. First, borrowers would increase the quantity of funds demanded for agricultural purposes from C_1 to C_2, and, if non-price rationing were not employed, would simultaneously receive a subsidy or income transfer (the concessionary transfer) of r_1rab.

Second, since money is fungible, credit can be borrowed ostensibly for agricultural purposes but diverted to such nonagricultural activities as consumption or investment. This gives rise to agricultural illusion—a situation where some agricultural loans have the appearance of going to that sector, but in fact go elsewhere. With the relatively lower interest rates for agricultural loans, it would be expected that borrowers would behave in this manner—especially those with multiple occupations and knowledge of other investment opportunities—and the demand for credit from agricultural lenders would shift right to $D_1D'_1$. Borrowers would want to use C_2C_3 quantity of credit to practice agricultural illusion and the total concessionary transfer now becomes r_1rac.

[1] The pioneering work on the concessionary interest rates formalized in this paper was done by Adams and Gonzalez-Vega 1976.

If further concessions were granted, e.g., r_2, r_3, etc., there would be yet further demand shifts to the right, such as $D_2D'_2$, $D_3D'_3$. The horizontal distance between any $D_iD'_i$ and DD' at any r_i would represent the amount of credit demanded to practice agricultural illusion due to the concessionary rate. Therefore, the locus of all equilibrium points for all r_i and $D_iD'_i$ traces the illusion demand curve for agricultural credit when concessionary interest rates are employed in that sector. It clearly demonstrates how agricultural illusion increases the concessionary transfer.

Delinquency provides another possibility for an income transfer. A "delinquency transfer" may be temporary, when farmers do not repay their loans on time, or permanent, when they never repay the loan. In the case of the temporary transfer, the farmer gains from improved income or reduced costs resulting from control over cash flow. The permanent transfer is equivalent to the real value of the loan principal plus real value of interest charges less any real amount repaid on loan and interest. In terms of figure 1, the amount of the permanent delinquency transfer would be the OC_3 loan principal plus Or_1cC_3 interest, assuming a concessionary interest rate of r_1, agricultural illusion and no repayment.

When inflation is present, a situation common to LDCs, the real rate of interest may be quite low or even negative. The effect is to enlarge the concessionary transfer and the temporary delinquency transfer (because of the lower real value of the loan when repaid). When inflation is anticipated by farmers, the amount borrowed will increase in accordance with the demand schedule and will further enlarge both transfers. For example, assume a concessionary rate of r_1, but farmers anticipated the real rate of r_2, because of inflation. Borrowers then would gain an additional concessionary transfer caused by inflation of r_2r_1ce and the potential for a permanent delinquency transfer of OC_4 loan principal and Or_2eC_4 interest. The higher the inflation, the greater will be these transfers. In the case of temporary transfers, the longer the delinquency, the greater the transfer.

Clearly the concessionary and delinquency transfers themselves and the additions to these transfers resulting from inflation are to be coveted. Therefore, a government with its control over agricultural credit institutions can use these potential transfers to induce certain types of economic activity and/or to reward certain behavior among borrowers. Moreover, borrowers in their competition for access to, and a share of, the transfer, undoubtedly will be willing to bargain with the government. Thus, there is an interplay between government and farmers in which political factors may take on considerable importance.

Heavy delinquency rates may be symptomatic of the degree that political factors have entered into the loan. When the government does not take the legally available measures to bring pressure on the borrower to repay, this indicates an unwillingness to bear the administrative costs or political consequences of such action.

The sheer existence of the concessionary transfer, and the possibility of an easy delinquency transfer, creates a potential for corruption. Government officials could easily appropriate part of the transfer for themselves by directly or indirectly lending to themselves, or by receiving kickbacks from borrowers.

Consequences

The consequences of using credit as a political instrument will vary depending on the specific situation in any country. It is possible, however, to draw generalizations about expected consequences in four areas: (*a*) resource allocation, (*b*) income distribution, (*c*) institution financial viability, and (*d*) economic development.

Apart from political considerations, the concessionary interest rate policy leads to a nonoptimal social allocation of (*a*) credit, (*b*) other resources, and (*c*) the production of goods in society, unless there is an effective means of non-price rationing. Experience demonstrates, however, that non-price-rationing schemes are difficult to enforce. The schemes are even more unworkable when political factors intervene. If inflation is present, the additional transfer due to inflation enhances the attractiveness of using credit for political objectives. If this occurs the resource allocation consequences are exacerbated. For example, it may encourage speculative investments and inventory stockpiling as well as agricultural illusion.

Access to the concessionary transfer (Gonzalez-Vega, 1977) and the delinquency transfers as a result of borrowing or corruption will gain at the expense of others. Inflationary conditions will increase the benefits of those who receive these transfers. The net result,

under any combination of the several transfers, is that the borrower gains income at the expense of the taxpayer or saver whose money is utilized to provide credit. Moreover, the borrower will gain income relative to those who have no credit or who borrow at true market rates of interest. Where the source is foreign, these effects have international implications as well.

Concessionary interest rates lead to lower interest revenues with the lending institution if the demand for credit is inelastic and/or the supply of loanable funds is restricted over the relevant range of the demand schedule. This, in combination with the well-recognized high costs of administering agricultural credit programs, will seriously jeopardize a credit institution's financial viability. Further, political lending will lead to erosion of loan funds caused by extensive delinquency inherent in such loans. The result is that, to cover costs and maintain or increase its loanable funds, the institution must be subsidized by government or obtain foreign loans or assistance. Without such supports, the institution's financial resources soon would be gone.

Finally, although it is well beyond the scope of this paper to discuss them in detail, it should be noted that there will be additional indirect impacts of credit allocation on general economic development, such as balance of payments, government expenditures and revenues, price stability, rural-urban migration, and sectoral development.

The Role of Foreign Donors

Foreign economic assistance programs contribute to the use of credit as a political instrument in two ways. First, they have provided considerable economic assistance for agricultural credit programs (Adams). Second, they have promulgated the policy of concessionary interest rates with the direct effect of creating concessionary transfers. As a consequence, they have been an indirect contributor to the use of credit for political purposes. This is particularly true for loans which have been made for general agricultural sector development, where credit typically flows to the larger and more sophisticated farmers and agricultural illusion takes on large dimensions. However, even in cases where foreign aid funds are earmarked for small farmers, the additional funds increase the size of the lenders' total portfolio and may permit some substitution for other funds previously directed to small farmers, thus releasing them for other purposes, including political.

Can Interest Rates Be Raised and Defaulting Reduced?

The obvious economic solution to prevent all these distortions is to raise interest rates and decrease default. Why, then, have policies of higher rates not been put into effect? Furthermore, why do not many lenders use their legal powers to limit default? The suggested answer is that the political cost is too great. First, governments would lose attractive elements available to them to bargain for political support. Second, farmers accustomed to the concessionary and/or default transfers would stand to lose substantially. In particular, the impact would fall on the larger and more influential farmers who practice agricultural illusion with access to alternative investment-consumption activities. Third, where corruption occurs, government officials would lose their access to these sources of income.

The Case of Bolivia

The framework is applied to Bolivia during the period of the government of General Hugo Banzer, 1971–78. (For a good discussion of the political developments in Bolivia over this period see Mitchell as well as Malloy and Borzutsky.)

The regional distribution of agricultural credit since 1971 was highly skewed to the tropical lowlands in the department of Santa Cruz. Between 1973 and 1978, 68% of commercial bank loans went to that department (private communication from Banco Central de Bolivia). Between 1971 and 1978, 64% of the volume but only 23% of the number of BAB loans went to Santa Cruz.[2] In contrast, according to the 1976 General Population Census, only 12.6% of the rural population lived in that department. Further, for the period 1964–71, only 43% of Bolivian Agricultural Bank (BAB) credit from regular credit lines went to Santa Cruz.

Several interdependent factors explain the

[2] Data from Departamento de Planificación, Unidad Estadística, from Banco Agrícola de Bolivia. All data reported in the remainder of this paper come from this source unless otherwise indicated.

highly disproportionate share of agricultural credit going to Santa Cruz in the Banzer period. First, the petroleum and agricultural boom in the region was viewed as the leading edge of the Bolivian economy. Rapid gains in food import substitutes and agricultural exports were expected from commercial farms whereas these possibilities were not foreseen for the small-scale traditional farming areas in the highlands. Second, geopolitics was another factor. With the new petroleum development, Bolivia viewed the growth of Santa Cruz as a buffer to further encroachment by Brazil, which had previously taken considerable territory in the rubber boom of 1899.

Whereas both of these factors were important in explaining the disproportionate credit flows, we suggest that domestic political factors were also important in the credit allocation. President Banzer had risen to power in a military coup with the support of a coalition of interests that included farmers in Santa Cruz (Mitchell, pp. 122–3). Hence Banzer was obliged to these persons not only for his sudden rise to power but also for their continued political support.

Institutional and Policy Structure

Over the 1971–78 period, 59% of the banking credit in Bolivia came from BAB. In addition, the government-owned State Bank, a commercial bank, loaned approximately another 20%. The system was amenable to government control. Credit was employed as the major agricultural sector policy instrument to "lead" agricultural production by means of a number of special credit programs established by the government and donors of foreign aid. Key features of credit policy were concessionary interest rates and central bank rediscounts to the banking system from special credit lines for agriculture.

Foreign assistance played a major role by providing a steady inflow of funds which freed government funds for loans to some major enterprises, such as cotton (little foreign assistance was used for this crop), as well as for liquidity which the institutions needed in view of soaring and heavy delinquency. From 1967 to 1978, there were $146 million (all figures in this paper are reported in current U.S. dollars) in foreign assistance committed for agricultural credit. A conservative estimate is that at least 45% of bank credit (BAB and commercial banks) came from this source.

Concentration of Credit

Over the 1971–78 period, BAB loaned $80.9 million in Santa Cruz with 3,348 loans. Of this amount, $45.9 million went to cotton in a total of 726 loans. A much smaller amount, $4.1 million, was directed to 118 farmers for soybeans. The average size loan for cotton and soybeans was $63,169 and $34,525, respectively, much larger than the $5,287 national average. Credit for the two crops, which represented 41% of the national BAB loan portfolio, went to only a few farmers (6% of BAB loans). These loans were made primarily to the larger farmers of Santa Cruz, many of whom belonged to that region's elite and to powerful regional interest groups such as ADEPA (The Cotton Growers Association).

Income Transfers

As shown in table 1, the recipients of BAB cotton and soybean loans received total income transfers of at least $44.5 million over the period, an amount only slightly less than the $49.9 million of principal originally loaned. The average transfers for cotton and soybean loans were $55,000 and $39,000, respectively.

These transfers result in part from interest rate concessions of 12% to 15% for BAB clients relative to the rates charged by commercial banks for commercial loans. Because the commercial rates are maximum rates established by the Central Bank, they are likely to be less than the true opportunity cost of

Table 1. Concessionary and Delinquency Transfers Associated with Cotton and Soybean Loans of Bolivian Agricultural Bank, 1971–1978 (in Thousands of U.S. Dollars)

	Cotton	Soybeans
	thousands	
Loan volume	45,861	4,074
Number of loans	726	118
Average loan size	63	35
Percent past due, 31 Dec. 1978	51	69
Delinquency transfer		
Interest and commissions	3,342	418
Principal	23,491	2,823
Concessionary transfer	5,680	519
Transfers due to inflation	7,399	829
Total transfer	39,912	4,589
Average transfer per loan	55	39

credit. To the extent this holds true, the concessionary transfer is understated.

The effect of inflation is to reduce the real interest rate and therefore to provide an additional transfer to the borrower. With the exception of 1973 and 1974, inflation in Bolivia was mild, yet the income transfer associated with inflation was substantial, estimated at $8.2 million.

From 1971 to 1978, BAB delinquency worsened. At the end of 1971, 15% of the loan portfolio was overdue; at the end of 1978, it was 43% overdue after reaching a high of 47% in 1977. Had many loans not been refinanced or extended, the situation would have been much worse. During 1978, 776 loans were extended. Furthermore, several BAB loans have been extended many times. The delinquency is concentrated in Santa Cruz: in 1978, 68.8% of the total BAB delinquency was in that department. In Santa Cruz, 48% and 52%, respectively, of loan numbers and volume were past due compared to 27% and 43%, nationally. Both cotton and soybeans contributed to the high proportion of loan volume delinquency.

At the end of 1978, the delinquency transfer associated with cotton and soybeans was $30.1 million. Before June 1977, the government would not permit the BAB authorities to pressure farmers for repayment. Also, to keep some private commercial banks from pressuring farmers, the government issued Supreme Decrees to buy these banks' delinquent portfolios and transfer them to BAB. In June 1977, Banzer issued a Supreme Decree which extended all BAB and State Bank cotton and soybean loans for periods of eight to twelve years. If the loans are paid back as scheduled, the borrowers will pay back virtually nothing in terms of real value due to the depreciating effects of inflation—the equivalent of a permanent income transfer.

The large BAB income transfers for borrowers for the two crops in Santa Cruz cannot be entirely attributed to political factors. Poor client selection, bad weather, insects, and marketing are other reasons. But even in cases of the latter, political intervention led to sizeable transfers. For example, in 1973, BAB and commercial banks financed large quantities of cotton, and ADEPA made forward contracts to sell cotton on the world market. When the world price exceeded the forward price, ADEPA refused to sell. The government supported them as Banzer established a minimum price by Supreme Decree. The world buyers refused to pay this higher-than-contracted price and much cotton remained unsold while delinquency soared.

The case of BAB is illustrative of what also happened in the State Bank. Unfortunately, inadequate data do not permit a breakdown of transfers for credit from that institution. They are, however, sizeable. This institution also began to lend heavily for cotton and soybeans in Santa Cruz after 1972. By 1977, they had discontinued lending to agriculture because of heavy delinquency. In 1978, they had $22.4 million in 232 past-due loans, most of which were for cotton and soybeans. (Private communication from the Banco del Estado.) Clearly, income transfers associated with these loans were also very substantial.

Consequences

The effect of credit being used as a political instrument to benefit the Santa Cruz commercial farming elite undoubtedly contributed to political stability during the Banzer reign. However, the elite's access to credit and the associated income transfers gave them a larger share of national income. Their ability to practice agricultural illusion through investment in real estate, commerce, and conspicuous consumption further enhanced their income and worsened regional and personal income distribution. For example the highland peasants gained little, and if it had not been for foreign aid for small farmer credit, which began in 1975, it is doubtful that this large mass of farmers would have received much credit at all. It is plausible that such inequities were important factors in the defeat of the government's candidate in the 1978 elections.

The long-run viability of financial institutions was seriously harmed. After 1976, the State Bank withdrew from agricultural lending because of the high costs associated with its heavy delinquency. In March 1979, BAB had to be rescued from bankruptcy by the government when it issued $41.5 million in bonds (El Diario) which permitted BAB to meet its financial obligations.

Conclusions

It should not be surprising that government-controlled credit institutions and policy can be used for political objectives although they are

cast in the context of economics. Credit as a political instrument is attractive to a government because it is rapidly implementable and has the appearance of going for worthwhile economic objectives but in reality offers opportunities for considerable benefits to borrowers by means of income transfers and gains from fungibility. Moreover, because the true benefits are hard to identify, they are less subject to the scrutiny of the opposition and the general public.

The usefulness of the present study is to provide a theoretical framework to show the use of agricultural credit as a political-economic instrument particularly where concessionary interest rates and permissive default are employed. The Bolivian case clearly illustrates the political economy of credit as it was applied by Banzer in 1971 to 1978. It also shows the unintended role of foreign assistance in abetting the use of credit in a political context.

The Bolivian case is not unique. It is likely that political forces figure strongly in credit allocation decisions in most nations. While they may contribute to political stability, they are subject to abuse and have undesirable consequences for resource allocation, income distribution, and financial institution viability. The degree to which credit can be used as a political instrument would be substantially reduced if concessionary interest rates were eliminated, a tougher stance on default were taken, and inflation reduced.

The voluntary implementation of the required interest rate and default policies will be difficult to attain given the high costs to governments in the loss of a political instrument. Therefore, pressures will have to be exerted by foreign donors in an appeal to improve resource allocation, income distribution, and financial institution viability.

Market Intervention Policies for Increasing the Consumption of Nutrients by Low Income Households

Richard K. Perrin and Grant M. Scobie

There is an immense step in passing from theory to governmental applications . . . and if this essay is of any practical value, it will be chiefly in making clear how far we are from being able to solve, with full knowledge of the case, a multitude of questions which are boldly decided every day.
—Augustin Cournot, 1838

This study employs a market equilibrium displacement approach to examine the nutrient consumption effects of market intervention programs such as food subsidies, income transfers, and agricultural input subsidies. The results permit comparison of the direct treasury costs of achieving marginal increases in nutrient intake with alternative programs. When applied to a case study of the food markets and population of Cali, Colombia, it was found that a marginal increase in caloric intake among the poor could be achieved at lowest cost with a consumer subsidy of certain cereals, although black market activity might raise this cost to that of an income subsidy.

Key words: Colombia, food policies, nutrient consumption, treasury costs.

Throughout much of the postwar period, the objectives of development were expressed in terms of economic growth. Through rapidly rising national products, real income gains were expected to accrue (albeit with the same lag) to an increasingly wider spectrum of the population. Gradually, marginal participants would be drawn into the mainstream of economic activity with part of the increments in real income being spent on additional food. In short, policies which stimulated overall economic growth were seen to be conducive to generally rising living standards including increased nutrient intake. Few if any countries had explicitly formulated, or funded, national nutrition programs.

Whether through disillusionment or impatience with the previous strategies, development objectives have been evolving which are much more narrowly focused (Selowsky 1979). The direct provision of food, education, health services, sanitation, and housing have become part of the "basic human needs" approach to aid and development. Governments have sought instruments with which they can effect changes directly in some specific target. Improved human nutrition is one such target (Scandizzo and Knudsen).

Economic research has been directed to measuring the magnitude of the malnutrition problem (Reutlinger and Selowsky) and its impact on physical, intellectual, and economic development (Selowsky 1978, Selowsky and Taylor). Other research has explored the possibilities for achieving nutrition goals through such government interventions as food price subsidies for the poor (Reutlinger and Selowsky; Ahmed; Kumar; George), income transfers to the poor (Pinstrup-Andersen and Caicedo), agronomic research (Pinstrup-Andersen, Ruiz de Londoño and Hoover), and agricultural production subsidies (Barker and Hayami; Hayami, Bennegan, Barker).

The purpose of the research reported here is to examine and compare the treasury costs of achieving specified nutritional goals through

alternative intervention programs such as those above, both in general and in a specific case study of consumers in Cali, Colombia. Given the magnitude of current intervention efforts in various countries,[1] such a comparison may prove to be quite valuable in assessing the impact of alternative policies.

Analytical Model

To permit comparison of the wide variety of intervention policies available, we find it convenient to group them into three categories: those which shift supply to the right, those which shift demand to the right, and those which drive a subsidy or wedge between producers' price and consumers' price. Figure 1 illustrates, for example, how an increase in food consumption from Q to Q' could be achieved either by a supply shift from S to S', by a demand shift from D to D', or by a market wedge of size W under which producers would receive price P'_1 while consumers would pay price P'_2. While not all possible market intervention policies can be directly represented by this analytical framework (such as certain types of food stamp programs), a great many can be. For example, supply shifting interventions can include (*a*) public investment in agricultural research which generates new information and technologies, (*b*) public investment in rural infrastructure, (*c*) direct subsidies of agricultural inputs, and (*d*) food import policies. Policies which shift demand can include (*a*) direct income transfers, (*b*) certain types of food stamp programs, or (*c*) nutrition-oriented consumer education programs. The price wedge approach can be used to describe a number of kinds of subsidy mechanisms, such as simple food stamp plans, ration shops, and bounties paid to producers.

To complete the analytical framework necessary to compare these policies, we first develop a model describing the price and quantity equilibrium displacement effects of each of the three basic types of policy instruments, for an n-commodity food economy with a malnourished ("poor") consuming sector and an adequately nourished ("rich") consuming sector. Given the nutrient content of these commodities,[2] the effect of the policies on equilibrium nutrient intake follows directly. We then examine in more detail the effect of income transfers and price wedges in order to compare their cost effectiveness in terms of the treasury costs associated with increments in nutritional improvement. In this paper we do not address issues related to the financing of such interventions, nor do we consider the potential effect of these public financing activities on food markets.

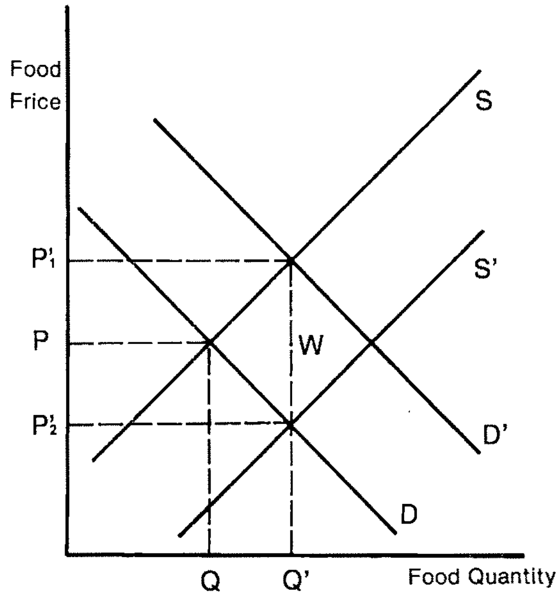

Figure 1. Increase food consumption via a supply shift, a demand shift, or a market wedge

Equilibrium Displacements Caused by Shifts in Demand, Supply, or Market Wedges

First consider the n-demand curves for the consuming population as a whole (we later stratify consumers into rich and poor strata). Changes from initial equilibrium levels of consumption of commodity i must result from either a shift in demand for that commodity or from a change in the price of either commodity i or one of the other commodities. The percentage change in quantities demanded can conveniently be expressed as

$$(1) \qquad Eq_i = \sum_{j=1}^{n} \eta_{ij} Ep_j^d + \gamma_i Ey,$$

where $i = 1, \ldots, n$; E is the percentage

[1] Subsidies on staple foods constitute a substantial proportion of total expenditures by some governments. "In Egypt, Korea, and Sri Lanka, food subsidies accounted for as much as one-fifth of total expenditure in 1974 or 1975, while several other countries devoted approximately one-tenth of expenditure to this component" (Davis). From a study of Egyptian food subsidies, Taylor (p. 35) reports that in 1975, staple food subsidies (on wheat, maize, sugar and edible oil) amounted to over 11% of gross domestic product.

[2] In this study, we consider only calorie consumption as a measure of nutrition, because of its importance as a limiting nutrient (Reutlinger and Selowsky). The equilibrium displacement model could quite easily be extended to consider a vector of several nutrients.

change operator,[3] η_{ij} are the direct and cross-price elasticities of demand, γ_i is the income elasticity of demand, and y denotes income. The effect of food stamp or nutritional education programs could be represented by a reinterpretation of the demand shifter ($\gamma_i Ey$).

Supply changes can be represented as

$$(2) \qquad Eq_i = \sum_{j=1}^{n} \epsilon_{ij} Ep_j^s + \delta_i,$$

where $i = 1, \ldots, n$; ϵ_{ij} are supply elasticities and δ_i is a supply shift caused by some policy. Such policies might include input subsidies (as in Barker and Hayami) or investment in agricultural research (as in Pinstrup-Andersen, de Londoño, Hoover). In work not reported here, we have used the model that follows to derive analytical solutions comparable to both these studies.

To incorporate the possibility of price subsidies, we specify the following equilibrium relationship between supply prices and demand prices:

$$(3) \qquad Ep_i^s = Ep_i^d + E\beta_i,$$

where $i = 1, \ldots, n$; $E\beta_i$ is the size of the subsidy wedge for commodity i, measured as a percentage of initial equilibrium price. These three sets of n equations each can be expressed in matrix notation as

$$(4) \qquad \begin{bmatrix} -H & 0 & I \\ 0 & -S & I \\ -I & I & 0 \end{bmatrix} \begin{bmatrix} EP^d \\ EP^s \\ EQ \end{bmatrix} = \begin{bmatrix} \Gamma Ey \\ \Delta \\ EB \end{bmatrix},$$

where H is an $n \times n$ matrix of demand elasticities, η_{ij}; S is an $n \times n$ matrix of supply elasticities, ϵ_{ij}; P^d is an $n \times 1$ vector of demand where P_p^d, P_r^d are $n \times 1$ vectors of demand prices by stratum; Q_p, Q_r are $n \times 1$ vectors of quantities by stratum; V_p, V_r are $n \times n$ diagonal matrices with the share of the com- prices, p_i^d; P^s is an $n \times 1$ vector of supply prices, p_i^s; Q is an $n \times 1$ vector of quantities, q_i; Γ is an $n \times 1$ vector of income elasticities of demand, γ_i; Δ is an $n \times 1$ vector of supply shifts, δ_i; and EB is an $n \times 1$ vector of price subsidies, $E\beta_i$.

The solution to the system of equations (4) expresses changes in equilibrium prices and quantities as functions of the policy variables, Ey, Δ and EB:

$$(5) \qquad \begin{bmatrix} EP^d \\ EP^s \\ EQ \end{bmatrix} = \begin{bmatrix} (S - H)^{-1}(\Gamma Ey - \Delta - SEB) \\ (S - H)^{-1}(\Gamma Ey - \Delta - HEB) \\ H(S - H)^{-1}(SH^{-1}\Gamma Ey - \Delta \\ \quad - SEB) \end{bmatrix}$$

Given these changes in the equilibrium consumption of commodities, the percentage change in the equilibrium level of nutrient consumption (calories in our case) is

$$(6) \qquad EC = KEQ = KH(S - H)^{-1} (SH^{-1}\Gamma Ey - \Delta - SEB),$$

where K is a $1 \times n$ vector of k_i, the fraction of initial total calorie consumption provided by commodity i.[4]

We have now established the functional relationship between the policy variables and the target variable (nutrient intake) for the simple case in which demand shifts (ΓEy) and price subsidies (EB) apply to the entire consuming population. But income transfers and price subsidies often will apply to only a subset of the population, so we must stratify the demand equations. Equation (1) is replaced by separate demand equations for the poor and the rich strata. The solution to this expanded system of equations,[5] which can be derived in a manner analogous to (5), is

$$(5a) \qquad \begin{bmatrix} EP_p^d \\ \\ EP_r^d \\ \\ EP^s \\ \\ EQ_p \\ \\ EQ_r \\ \\ \end{bmatrix} = \begin{bmatrix} (S - H)^{-1}[V_p\Gamma_p Ey_p + V_r\Gamma_r Ey_r - \Delta - \\ (S - V_rH_r)EB_p - V_rH_rEB_r] \\ (S - H)^{-1}[V_p\Gamma_p Ey_p + V_r\Gamma_r Ey_r \\ - \Delta - V_pH_pEB_p - (S - V_pH_p)EB_r] \\ (S - H)^{-1}(V_p\Gamma_p Ey_p + V_r\Gamma_r Ey_r \\ - \Delta - V_pH_pEB_p - V_rH_rEB_r) \\ H_p(S - H)^{-1}[(S - V_rH_r)H^{-1}\Gamma_p Ey_p \\ + V_r\Gamma_r Ey_r - \Delta - (S - V_rH_r)EB_p - V_rH_rEB_r] \\ H_r(S - H)^{-1}[(V_p\Gamma_p Ey_p + (S - V_pH_p) \\ H_r^{-1}\Gamma_r Ey_r - \Delta - V_pH_pEB_p - (S - V_pH_p)EB_r] \end{bmatrix},$$

[3] The percentage change in a variable x, represented as $E(x)$, can be defined as $E(x) = d\ln(x) = dx/x$.

[4] Note that the results of the solutions (5) and (6) can be interpreted as point elasticities. Equation (6), for example, expresses the percentage change in equilibrium calorie consumption as a linear function of, say, δ_i, which is the percentage shift in the supply of commodity i. The slope $dEC/d\delta$ is the point elasticity of the effect of δ_i on EC, which will be correct only to a first-order linear approximation for any noninfinitesimal δ_i.

[5] The derivation of this solution can be obtained from the authors.

modity consumed by the stratum displayed or the diagonal, v_{pi} and v_{ri}. Also, H_p, H_r are $n \times n$ demand elasticity matrices by stratum; H is defined as $V_pH_p + V_rH_r$; Γ_p, Γ_r are $n \times 1$ vectors of income elasticities by stratum; Ey_p, Ey_r are percentage changes in income by stratum; EB_p, EB_r are $n \times 1$ vectors of price subsidies by stratum.

The percentage change in the equilibrium level of calorie consumption in the poor stratum is then

$$\text{(6a)}\quad EC_p = K_pEQ_p = K_pH_p(S - H)^{-1} [(S - V_rH_r)H_p^{-1}\Gamma_pEy_p + V_r\Gamma_rEy_r - \Delta - (S - V_rH_r)EB_p - V_rH_rEB_r],$$

where K_p is the $1 \times n$ vector of calorie consumption weights in the poor sector.

Treasury Costs of Achieving Consumption with Income Transfers

Direct income transfers to the poor sector will shift the demand for each commodity (by the poor sector) outward by the proportion γ_iEy_p. The net equilibrium nutritional impact of an income transfer to the poor, EC_p/Ey_p, we will refer to as the total income elasticity of calorie consumption. From (6a), the total income elasticity of calorie consumption by the poor is

$$\text{(7)}\quad \frac{EC_p}{Ey_p} = K_pH_p(S - H)^{-1}(S - V_rH_r)H_p^{-1}\Gamma_p = -K_pZH_p^{-1}\Gamma_p$$

where $Z \equiv -H_p(S - H)^{-1}(S - V_rH_r) = -H_p [I - (S - V_rH_r)^{-1}V_pH_p]^{-1}$.

Intuitively, this elasticity will consist of two parts, the first being the direct consumption effect of increased incomes among the poor, which Reutlinger and Selowsky refer to as income elasticity of demand for calories. The second part will be a dampening effect on consumption, resulting from price increases as the market system adjusts to the higher demand for food by the poor.

The first part, the income elasticity of demand for calories, can be determined as a special case of (7) in which the elements of S approach infinity, i.e., perfectly elastic supplies. In this special case, $Z = -H_p$, and the income elasticity of demand for calories is, thus,

$$\text{(7a)}\quad \frac{EC_p}{Ey_p} = K_p\Gamma_p = \sum_{i=1}^{n} k_{pi}\gamma_{pi}.$$

Thus the income elasticity of demand for calories is just the weighted sum of income elasticities of demand for commodities, with the weights being the proportion of the poor's calories provided by that commodity. This is the result obtained by Pinstrup-Andersen and Caicedo (p. 403).

The other limiting case of interest is that for perfectly inelastic supplies, $S = 0$, in which case any extra food consumption by the poor can only be obtained by reduced consumption among the rich. In this case,

$$Z = -H_p[I + (V_rH_r)^{-1}V_pH_p]^{-1} = -[I + H_p^{-1}(V_rH_r)^{-1}V_p]^{-1}H_p,$$

so (7) can be written as

$$\text{(7b)}\quad \frac{EC_p}{Ey_p} = K_p[I + H_p(V_rH_r)^{-1}V_p]^{-1}\Gamma_p.$$

This is the analytical solution for the results obtained by Pinstrup-Andersen and Caicedo [eq. (7), p. 405].

In measuring costs, we shall, for the purposes of this paper, ignore administrative costs and any social costs in terms of welfare triangles or other measures. The direct treasury costs of an income transfer Ey_p will of course depend upon the initial per capita income of the poor, y_p, and the number of poor persons. The treasury cost on a per-poor-person basis is simply

$$\text{(8)}\quad Gy = y_pEy_p,$$

or, given the relationship between Ey_p and calorie gain in equation (7), per person treasury costs can be expressed directly as a function of calorie gains EC:

$$\text{(9)}\quad Gy = y_p(k_pZH_p^{-1})^{-1}EC_p.$$

Note that this is a linear relationship, i.e., an additional 1% increase in calorie consumption can be achieved at constant cost in terms of the fraction of current income required as an income transfer.

Treasury Costs of Achieving Consumption with Food Price Subsidies

We derived, in equation (6a), the nutritional impact of food subsidies offered only to the poor consumer stratum. Before we examine the treasury costs of such policies, we should point out that the results of equation (6a) will hold only if the poor do not take advantage of the arbitrage opportunity to purchase food at the subsidized price and sell it to the rich con-

sumer sector via a black market.[6] If such arbitrage were costless and if it occurred freely, the rich would tend not to buy any food on the open market, but instead would pay the black market price. The effect would then be for the entire consumer market demand to be channeled through the poor, so that the government in effect would subsidize the entire consumer sector, with results described by equation (6) rather than (6a).[7] Now, since arbitrage cannot be costless, one could not expect complete arbitrage to occur; but neither would one anticipate a total absence of arbitrage, as is implied by the results of equation (6a). While it would be of interest to describe more fully the equilibrium results as a function of the costs of or the extent of arbitrage, we have not done so. Instead, we will simply describe the results of the two extreme cases—a general subsidy to all consumers versus a subsidy only to the poor in which no arbitrage takes place.

The treasury cost of general (i.e., for all consumers) price subsidies is equal to the amount of each subsidy, $p_iE\beta_i$, times final quantity, $q_i(1 + Eq_i)$, or

$$(10) \quad G_B = \Sigma p_i q_i E\beta_i(1 + Eq_i) = \Sigma p_i q_i E\beta_i + \Sigma p_i q_i E\beta_i Eq_i,$$

or, in matrix notation,

$$(10a) \qquad G_B = EB'R\lambda + EB'REQ,$$

where R is the $n \times n$ diagonal matrix with the diagonal elements consisting of initial expenditures (p_iq_i) on the ith commodity, and λ is an $n \times 1$ vector of 1's. The change in quantities EQ, resulting from price wedges EB, is obtained from equation (5) and is substituted into (10a) to yield the cost equation

$$(11) \quad G_B = EB'R\lambda - EB'RH(S - H)^{-1}SEB.$$

By similar derivations, the treasury cost of a subsidy only to the poor sector can be expressed as

$$(12) \quad G_{Bp} = EB'_pR_p\lambda + EB'_pR_pZEB_p,$$

where R_p is the $n \times n$ diagonal matrix of food expenditures by the poor.

[6] Ahmed (p. 40) cites evidence of such arbitrage under the dual price system for rice in Bangladesh.

[7] This assumes that the government makes available any quantity that is demanded at the subsidized price. In Bangladesh, allotments of subsidized grain sometimes exceed household consumption (Ahmed, p. 40).

Now it is not possible to establish a direct one-to-one relationship between the treasury costs of subsidies and calorie gains achieved, because there are many values of the subsidy vector EB which could achieve a given calorie gain [see eq. (6a)]. One might naturally be interested in that subsidy vector EB which achieves a given calorie gain at lowest treasury costs, but we do not pursue that issue here. However, there will be a one-to-one relationship between treasury cost and calorie gain if the subsidy is uniform for all foods or for a subset of food commodities. In this case, the vector of subsidies can be represented as $EB = \pi E\beta$, where π is a vector consisting of zeros for commodities not subsidized and ones for commodities subsidized, and where $E\beta$ is a scalar representing the size of the uniform subsidy.

First consider a uniform subsidy for all consumers. The treasury cost as a function of the subsidy is

$$(13) \quad G_\beta = E\beta\pi'R\lambda - \pi'RH(S - H)^{-1}S\pi E\beta^2.$$

Solve equation (6) for $E\beta$ and substitute into (13) to obtain treasury costs as a quadratic function of calorie gains:

$$(14) \quad G_\beta = \{-\pi'R\lambda[K_pH_p(S - H)^{-1}S\pi]^{-1}EC_p - \{\pi'RH(S - H)^{-1}S\pi[K_pH_p(S - H)^{-1}S\pi]^{-2}\} EC_p^2.$$

By a similar derivation, the cost of calorie gains with a uniform subsidy for the poor sector only can be derived as

$$(15) \quad G_{\beta p} = [\pi'R_p\lambda(K_pZ\pi)^{-1}]EC_p + [\pi'R_pZ\pi(K_pZ\pi)^{-2}]EC_p^2.$$

A special case of uniform subsidies of some interest is the subsidy of a single commodity i, which was examined in some detail by Reutlinger and Selowsky. If the supply and demand elasticity matrices are diagonal, as they assume, equation (15) can be reduced to an expression in terms of own-price elasticities as

$$(16) \quad G_{\beta i} = \frac{p_iq_i}{-k_{pi}\eta_{pii}}\left(1 - \frac{\eta_{ii}}{\epsilon_{ii}}\right)\left(EC_p + \frac{\eta_{ii}}{k_{pi}\eta_{pii}}EC_p^2\right).$$

This is exactly the result obtained and used by Reutlinger and Selowsky [eq. (25), p. 45]. Similarly, the cost of a "poor-only," single-

commodity subsidy with diagonal supply and demand elasticity matrices can be derived from (16) as

$$(17)\quad G_{\beta pi} = \frac{p_i q_{pi}}{-k_{pi}\eta_{pii}}\left[\left(1 - \frac{v_{pi}\eta_{pii}}{\epsilon - v_{ri}\eta_{pii}}\right) EC_p + \frac{1}{k_{pi}} EC_p^2\right].$$

The linear terms of either (16) or (17) indicate the relative marginal costs of achieving the first marginal units of calorie gains from subsidizing the commodity.

A Colombian Case Study

In this section the analytical model is used to examine potential intervention policies for the city of Cali, Colombia. Specifically, we wish to compare the cost effectiveness of an income transfer versus certain food subsidy schemes, for raising calorie consumption among the malnourished.

The general characteristics of the sample population are described by Pinstrup-Andersen, de Londoño, and Hoover (1976, table 1). They grouped the sample into five income strata. The lowest income group (with annual per capita income of \$60) we designate as poor (p). Their actual calorie intake of 1,904 calories per capita would have to increase by 12.36% to attain the recommended daily allowance (RDA) of 2,140 calories. The remaining four income categories we group together under the heading "rich" (r), because in each the average per capita calorie consumption approximately equals or exceeds the RDA. The annual per capita income of the lowest of these four strata is but \$107 (1970 dollars), which should serve to caution us from inferring more from these labels than calorie sufficiency.

We will use the results of the analytical model to examine the treasury costs of increasing the calorie intake of the poor both at the margin and by amounts up to 12.36%. In the study of this population, twenty-two food commodities were identified, as listed in table 1. The demand elasticity matrices as estimated by Pinstrup-Andersen for each of the strata were made available to us, permitting us to construct H_p and H_r corresponding to the poor and rich groups. No information about S, the supply elasticity matrix, was available, so we

have assumed it to be diagonal, with all elasticities equal. We examined results, using elasticity values of 0, 0.5, 1.0, and 2.0. As the results did not differ greatly, we present here only those results for the values of 0.0 and 1.0 for all supply elasticities.

The results presented in table 2 show that, except for the maize price subsidy (which is lowest in cost), the uniform subsidy of "all grain" provides the least-cost marginal increase in calorie consumption, followed by subsidies of other individual commodities and all foods together, the direct income transfer, and the general food subsidy for all persons, in that order. The results are not very sensitive to supply elasticity, since the poor stratum is in this case quite a small proportion of the population, and prices are not therefore greatly affected.

The cost per increase in calorie consumption attained with price subsidies rises with the amount of the calorie increase realized, because the cost functions [eqs. (12), (14), and (15)] are quadratic. As is evident from the plots of some of these costs functions in figure 2, however, the quadratic term does not cause a significant departure from linearity over the relevant range of calorie consumption increases. A more serious approximation error over this range arises from nonlinearity in the demand curves as the size of the subsidy increases. Our model utilizes point estimates of the elasticity of demand and generates point estimates of the elasticity of equilibrium displacement. As we examine finite equilibrium displacements, the model approximates changes in quantity demanded as $Eq = \eta Ep^d$ effectively by a linear demand curve over which η holds as an arc elasticity. The model itself provides no sensitivity analysis which permits us to determine the size of the errors introduced by departures of the demand curves from linearity. However, we have examined the subsidy limit at which the demand curves cross the horizontal axis, as an indication of where the estimates certainly become unrealistic. In the case of a maize price subsidy with unit supply elasticities, this limit occurs with a calorie increase of about $EC_p = .10$. That is, with linear demand curves exhibiting arc elasticities as shown in table 1, calorie consumption among the poor can be increased only about 10% if the maize is given away to the poor stratum. The comparable limits for subsidies of other commodities are even smaller. We conclude from this that our model does not accurately predict the equilibrium displacements from single commodity subsidies except for small increases in calorie consumption, say in the vicinity of 1% or 2%.

By contrast, the uniform subsidy of all grains (maize, rice, and other grains) requires a price reduction to the poor of "only" about 45% to achieve the full 12% increase in calorie consumption, and the uniform subsidy on all twenty-two commodities requires a price re-

duction of less than 20% to achieve that increase in consumption. Hence, approximation errors due to nonlinearity of demand and supply curves will be substantially smaller for subsidies of groups of commodities. Even so, this model is best suited to the prediction of equilibrium displacement from relatively small interventions in the market.

Recall that the predicted nutritional impact of these price subsidies to the poor would occur only if there were no arbitrage sales of subsidized food by the poor to the rich. We earlier argued that in the limiting case of complete and costless arbitrage, where all food purchases are channeled through the poor, the treasury costs and calorie gains would be the same as in the case of general price subsidy to the entire population. With a general uniform subsidy, the cost of achieving nutritional gain in the poor stratum would increase dramatically. The cost to achieve a given calorie target is about ten times the cost required for a "poor-only" subsidy for which arbitrage could be excluded. Figure 2 provides some indication of this dramatic increase.

To provide estimates to compare with other studies, we have used equation (7a) to determine that the income elasticity of demand for calories within the poor stratum is 0.63. Given unit supply elasticities, however, price increases would dampen this direct income effect, so that the total income elasticity of calorie consumption is [from eq. (7)] slightly lower, 0.60. For zero supply elasticities, the estimate falls further to 0.51. (This compares to an estimate of 0.54 implied by table 5 in Pinstrup-Andersen and Caicedo, which they derived from an iterative equilibration analysis of the same data). The price-dampening effect on income elasticity is small in this case study because the poor stratum comprises only 18% of the population, and their increased purchasing power has a modest effect on prices. Our estimate of 0.63 for income elasticity of demand for calories compares favorably with Ahmed's estimates of calorie expenditure elasticity among the poor of Bangladesh (0.5 to 1.37 for various strata within the poor). However, it is considerably higher than the estimate of 0.19 given by Reutlinger and Selowsky (p. 72) for all of Latin America. Their estimates apply to consumers as a whole, rather than just to the poor strata, and they based their estimates on national aggregate consumption data rather than on household data.

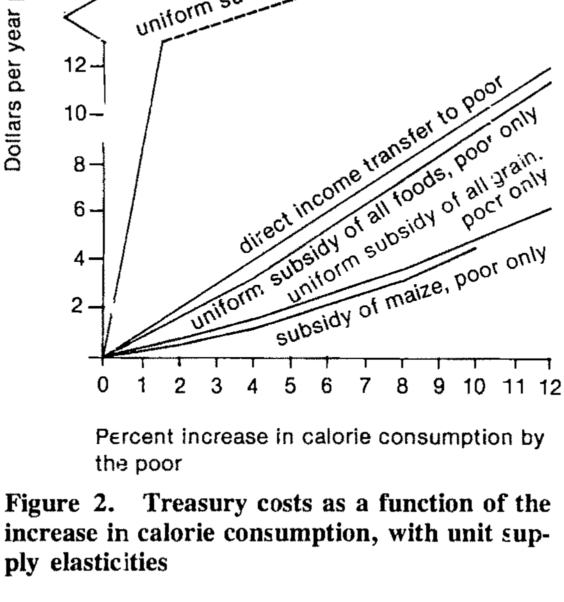

Figure 2. Treasury costs as a function of the increase in calorie consumption, with unit supply elasticities

Summarizing the results of this case study, it appears that the lowest-cost-feasible policy to achieve substantial increases in calorie consumption would be a price subsidy on grains, at an annual cost of about $.40 per poor person for each 1% increase in calorie consumption. A price subsidy for all foods for the poor could achieve the same results for about $.83 per person. However, arbitrage sales from the poor to the rich would raise the costs of such price subsidy programs; and it is quite possible that even with modest levels of black market activity, the cost of achieving the calorie target with price subsidies could exceed the $1.00 annual cost per person for achieving each 1% gain using a direct income transfer.

Summary and Conclusions

We have developed an analytical model of equilibrium displacement with which the effects of a wide variety of food market intervention policies can be evaluated and compared. This model derives point elasticities of nutrient consumption in response to market wedges or to shifters of demand and supply.

These elasticities are then used to determine treasury costs as a function of increases in nutrient consumption, for various intervention policies.

We used the results of this model to examine the case of consumers in Cali, Colombia. Information was available by income stratum on demand elasticities and food expenditures, together with data on the caloric content and prices of twenty-two food commodities. For the poorest income stratum (the only one for which average per capita caloric consumption was below the target level of 2,140 calories per day), we calculated the income elasticity of demand for calories to be .63, and the total income elasticity of calorie consumption (including equilibrium price adjustment effects) to be .60. Including these price adjustment effects, we determined that to achieve each 1% increase in calorie consumption, the required annual per capita income subsidy would be about $1.00.

We found that a 1% increase in calorie consumption could be obtained with a price subsidy on all commodities for the poor at a treasury cost of about $.83 per person per year, which is slightly less than the cost of the income subsidy approach. It would be even less expensive to achieve marginal consumption increases by subsidizing certain commodities or groups of commodities, rather than to subsidize all food commodities equally. For example, a subsidy of the price of grains (rice, maize, and "other grains") would achieve a 1% consumption increase at an annual cost of only $.40 per person. The cost of any of these price subsidy schemes will be increased to the extent that black markets funnel subsidized goods through the poor sector into the rich sector.

In addition to the limitations of our model imposed by its linearity, there are other limitations of this approach which should not be overlooked. We have examined only the direct treasury costs of these intervention policies, ignoring administrative costs and social cost triangles or other measures of social welfare. We have ignored the issue of where government funds for intervention might be obtained and the impact that such fundraising itself would have on food markets. Finally, we have taken the noneconomic goal of increased calorie consumption as a given. The validity of this as a goal, versus simply an increase in real income as a goal, is certainly an issue for debate. Furthermore, increased calorie consumption may not be the best route to improved health status among the poor, given such alternatives as medical care, improved sanitation, or nutrition-oriented education of household decision makers (Franklin and Vial). However the approach of this study does provide some new insights and perspectives for examining the efficiency and costs of policies oriented toward increasing nutrient consumption in low income households.

Farm Level Economics of Soil Conservation in the Palouse Area of the Northwest

Oscar R. Burt

Control theory is applied to the farm level economics of soil conservation in a model which uses depth of topsoil and percentage of organic matter therein as the two state variables. An approximately optimal decision rule was tested against the optimal rule and found to be excellent; errors in the decision rule were less than one percent within the region in state space of practical consideration. Results suggest that intensive wheat production under modern farming practices and heavy fertilization is the most economic cropping system in both the short and long run in the Palouse Area except under low wheat prices.

Key words: control theory, dynamic programming, Palouse area, soil conservation.

In many respects, it appears that the economics of soil conservation has been a neglected subject in agricultural economics during the last two or three decades except as it relates to stream pollution and externalities. The most obvious reason for this apparent lack of interest in the subject is the view that advances in technology have made soil resources per se of less consequence for agricultural production. One outstanding example of the impact which technical change has had is in nitrogen fertilization since World War II.

In 1940, Ibach focused on topsoil in the Corn Belt as the critical resource determining value of agricultural land and used pounds of nitrogen per acre in the topsoil as a measure for estimating land values. With cheap sources of inorganic nitrogen made available by modern technology and its widespread use, this attention to topsoil as a source of nitrogen is largely obsolete. In a sense, topsoil was transformed by modern technology from a primarily stock resource into a largely renewable resource for purposes of practical decisions. But rising energy costs the last few years reemphasize the role of relative costs in delineating the important economic issues during any particular era.

In spite of advances in technology, those already experienced and forthcoming, economic trade-offs in soil conservation can be important. Economic knowledge in soil conservation, which is usually quite specific to localized areas and regions, could be important in national agricultural policy decisions (Benbrook), as well as useful information for improved resource allocation at the farm level. The primary purpose of the research reported here was to explore what could be learned by an application of modern economic methodology (control theory) to a region which is prone to soil erosion. In addition to these illustrative empirical results, it is shown that the approximation method given in Burt and Cummings (1977) works extremely well in applications to soil conservation.

The issue of externalities and social costs of sedimentation and pollution in streams has been avoided purposely in this study. But, insofar as soil losses impose these additional costs on society, there exists an incentive for government to subsidize soil conservation measures and/or to penalize farming systems which are relatively erosive on the soil.

The Wheat-Pea Area of the Palouse

The study area is what is commonly called the wheat-pea area of the Palouse, lying mostly in eastern Washington and western Idaho. The soil is rich, and precipitation is usually adequate to produce relatively high yields of wheat, but the topography is rolling hills with

Oscar R. Burt is a professor of agricultural economics and economics at Montana State University.

Montana Agricultural Experiment Station Journal Series no. 1099.

The author acknowledges financial support for this research from Resources for the Future, Inc.

steep slopes which create soil erosion problems when farmed. The average slope of the land is about 13%, but some of the steeper farmed slopes approach 50% (Pawson et al.). This region probably has the roughest topography of any area in the United States that is planted to significant acreages of wheat.

The soil is deep loess, with a soil mantle depth of over 100 feet, except in the bottoms of the draws where the minimum depth is about 10 feet. Therefore, soil erosion does not threaten the most basic soil resource, namely, the soil mantle of potentially productive parent material.

The primary hazards from soil erosion are gullying and loss of organic matter and topsoil. Depth of topsoil varies considerably in relation to slope and location on the hill. The tops of the hills have relatively shallow topsoils of less than 6 inches, with a relatively low percentage of organic matter. In general, the depth of topsoil increases with movement down the slopes of the hills, reaching 24 inches near the bottom, the average depth on the lower slopes being 21 to 24 inches. Percentage organic matter in the top 6 inches tends to increase with the depth of topsoil and averaged about 3.3% in 1960 (Pawson et al.).

Specification of the Model

Because soil losses are not a threat to the soil mantle itself on the loess soil of the study area, two state variables, (*a*) depth of topsoil and (*b*) percentage of organic matter in the top 6 inches of soil, would appear to capture the essential information in the dynamic optimization problem of soil conservation decisions. State variables in a dynamic optimization problem must encompass sufficient information on the decision process so that when the variables are at given levels at a point in time, the history of the decision process is almost completely subsumed for purposes of optimal decisions in the future. The state variables can hardly subsume all of the pertinent information on the history of the decision process, but must do so within the limits of approximations which are considered acceptable for an empirical model. The two state variables specified here will suffice if the soil at a given site is relatively homogenous in its vertical profile below the topsoil. Gullying is not a serious problem when farming practices are within the limits implied by the crop rotations allowed in this study.

Strictly speaking, there are many other state variables associated with plant nutrients and the soil chemistry, but these are swept aside and the focus is on variables more directly affected by erosion. Plant nutrients and various measures of the soil chemistry are affected by soil erosion, but physical soil losses and changes in organic matter (our two state variables) should indirectly measure a substantial part of the influence of erosion on individual nutrients and changes in the soil chemistry, as well as some of the changes in the biological base of the soil.

For a given soil (particular location), depth of the topsoil and percentage of organic matter taken jointly probably reflect general soil fertility quite well. This statement should not be construed to mean that these two variables explain most of the variation in fertility across locations because the basic parent material and other factors change across locations. In soil conservation decisions, the concern is with changes in productivity over time at a given site; thus, it is expected that the two state variables jointly reflect changes in fertility with sufficient accuracy if the fertilization, cultural practices, and crop rotations also are taken into account in the dynamic model.

Another important role of these two state variables is to measure indirectly soil structure, which is fundamental to soil aeration and permeability. In the steeply rolling hills of the Palouse, good water penetration of the soil is extremely important in crop production. Poor soil structure on steep slopes could seriously depress wheat yields because of poor utilization of rainfall. Soil structure also has a direct effect on the erosion process itself.

Decision variables encompass all possible farming practices and crop rotations which jointly affect soil organic matter, physical soil losses through erosion, and net cash flow from the land resource. "Lumpy" investments, such as construction of terraces, are not considered here, but the type of analysis undertaken is a prerequisite to economic analysis of such investments. Obviously, some method must be devised to reduce the number of decision variables to a feasible number, preferably one or two.

The empirical measures and data for this application came from Horner et al. and Pawson et al. Those measures and data largely determined the set of cultural practices and rotations to be considered. Fertilization and cultural practices were taken as given for a particular rotation, which relegated decisions

to a choice of rotations. It turned out that a single decision variable, percentage of the land in wheat, could be used by eliminating rotations that were dominated by others with at least as high net returns and less soil loss. Changes in organic matter are highly correlated with soil losses, which made the dominant rotations based on soil losses also dominant with respect to changes in organic matter. One exception was a rotation with high frequency of green manure crops. Net returns for this rotation were relatively low and it would appear to be relevant only under conditions of low organic matter. Rather than introduce a second decision variable, frequency of green manure crops, the simpler model with one decision variable was used.

Although the percentage of land area in wheat cannot be treated as a strictly continuous variable, the model was specified with a continuous decision variable so that an approximation procedure for dynamic optimization models could be evaluated precisely. If one is willing to interpolate between rotations already tested in experiments and small modifications in these rotations, then the measures required in the economic analysis can be estimated for many different levels of the decision variable (percentage of land in wheat). There is also an opportunity to use different rotations on several areas of the total farm and thus provide additional levels of the decision variable. Consequently, treatment of the decision variable as if it were a continuous variable is not a constraining or limiting assumption.

Crop rotations tend to be a rather static concept where a separate field is visualized for each year of the rotation. To be completely accurate, crops grown on various fields of the farm within the past few years would need to be introduced as state variables, and a decision variable would be required for each field to designate which crop to plant. Nevertheless, a model containing only depth of topsoil and percentage of organic matter as state variables, with average percentage of the land in wheat as a decision variable, will work well because the state variables change slowly over time. In fact, the discrete time period of the dynamic model could be specified as a five- or ten-year period without much loss in precision, but an annual model is used. The derived decision rule from the annual model can be interpreted rather loosely because crop rotations may be changed infrequently with essentially no loss in economic efficiency. The appropriate criterion is maximum present value of net returns from the land resource over an infinite planning horizon. If the farmer's planning period is finite, it is assumed that the market for land will reflect the implicit value associated with various levels of the state variables. The following notation is introduced: x is depth of topsoil in inches; y is percentage organic matter in the upper six inches of soil; u, percentage of land in wheat; r, the discount rate (in real terms adjusted for inflation); $\phi(u,x,y)$, annual soil loss function (inches); $h(u,x,y)$, annual organic matter loss function (same units as y); and $G(u,x,y)$, annual net returns function (dollars per acre). The dynamic optimization model can be stated as

$$(1) \qquad \sum_{t=1}^{\infty} G(u_t,x_t,y_t)/(1 + r)^t,$$

a maximum with respect to $u_1, u_2, \ldots$, subject to

$$(2) \qquad x_{t+1} = x_t - \phi(u_t,x_t,y_t),$$

$$(3) \qquad y_{t+1} = y_t - h(u_t,x_t,y_t).$$

Estimation of Functional Relationships

All of the empirical measures and data are taken from Pawson et al. and Horner et al. To some extent, the model had to be simplified to accommodate the limited information available, and the data base is about twenty years old.

In seeking data and/or the necessary functional relationships for an application in soil conservation economics, nothing comparable to the information in Pawson et al. and Horner et al. could be found, let alone in published form. Information on the dynamics of organic matter and its influence on crop yields is particularly scarce. For regions with a shallow soil mantle, one would need to quantify the influence of a declining root zone on crop yields. Because there are deep loess soils in the Palouse, there is no need to measure this influence.

The twenty-year-old data raise two questions: (a) Are relative prices and costs relevant today and in the future? (b) Has technology changed so much that the basic biological and physical relationships are no longer a good approximation? The problem of relative prices and costs is dealt with by considering a range of wheat prices while holding other prices and costs constant. A proportionate increase in all prices and costs will not affect optimal inter-

temporal allocation of soil resources, except for slight distortions in the short run emanating from such factors as fixed costs in machinery. More precisely, a proportionate increase in the net return function $G(\cdot)$ in equation (1) will have a neutral influence, as can be seen by the derived decision rule equation in Burt and Cummings (eq. 26, p. 16).

Because wheat price is treated as a variable parameter, it can be deleted from the discussion on relative costs and prices. Field peas and alfalfa hay are the other crops in the rotations considered. The analysis was done using 1958 costs and prices assumed by Pawson et al., \$3.50 per hundredweight and \$15.00 per ton for peas and alfalfa, respectively. These crop prices are about 25% less than the average prices received by farmers in Washington around 1958. Apparently because of the limited local market for hay and the dominance of the Palouse in the national market for field peas, Pawson et al. discounted these prices somewhat. The result is a bias against soil conservation.

The adjustment factor to transform costs into 1978 dollars is 2.66, based on prices paid by farmers for production items, taxes, interest, and wages. The average prices received by U.S. farmers during 1954–58 were \$4.67 per hundredweight and \$20.82 per ton for peas and alfalfa hay, respectively. Inflation of these prices by the factor 2.66 gives \$12.42 and \$55.38 for peas and hay. Average prices during 1974–78 were calculated for comparison, but the averaging was done in deflated dollars. Then the results were inflated to 1978 dollars because of the rapid rate of inflation during the period; the results were \$12.15 and \$64.24 for peas and alfalfa, respectively. Adjusted prices of peas in the two periods are almost identical, but the price of alfalfa is about 20% higher in the latter period. With respect to prices and costs in 1978 compared to 1958, we conclude that the price of alfalfa hay was enough greater in 1978, that the soil conservation analysis reported below is somewhat biased toward greater wheat production, and thus, more exploitive use of the soil resource. Of course, the critical unknown is long-run trends in relative prices and costs during the decades ahead.

In regard to the second question, dealing with technological changes, it would appear that the changes have been heavily weighted in the direction of larger wheat compared to alfalfa yields. However, greater wheat yields enter symmetrically with wheat price in determining gross returns from wheat, so that parameterization of wheat price can be interpreted as changed yield expectations with fixed price or a change in price with fixed yield.

Technological changes that lower production costs probably have been about equally distributed among the three crops used in the rotations. Cultural practices and levels of fertilization assumed in Pawson et al. were quite advanced for actual farming practices during that time; the level of elemental nitrogen fertilization was as high as 100 pounds per acre in the rotations used to develop empirical relationships for this study.

No attempt was made to project technological change into the future because it is such a multidimensional phenomenon that the effects on intertemporal allocation of soil could be either exploitive or conserving. Consequently, the functional relationships in (1) through (3) are assumed constant over time.

The data presented in table 18 of Pawson et al. (p. 51) on various crop rotations is used as the primary basis for determining the functions $G(u_t,x_t,y_t)$, $\phi(u_t,x_t,y_t)$, and $h(u_t,x_t,y_t)$, i.e., annual net returns, soil losses, and organic matter losses. Annual changes in organic matter for the first ten rotations in their table 18 are given in the last row of table 15 (p. 31); the changes are from a base of 3.3% organic matter. Comparable changes in organic matter from three of the remaining thirteen rotations of table 18 were obtained from a linear regression between organic matter changes and soil losses. The regression used only rotations that included alfalfa hay and winter wheat, because these rotations dominated the other rotations on the basis of net returns per unit of soil losses. Six rotations ultimately were selected as an empirical basis for estimating the three functions in (1), (2), and (3); these were the rotations associated with rows 3, 8, 10, 18, 20, and 23 in Pawson's table 18.

Relatively heavy nitrogen fertilization of wheat is assumed (Pawson et al., table 11, p. 27). Average depth of topsoil is 18 inches and average organic matter is 3.3%.

A relationship between wheat yields and the state variables is required, and this was available in Pawson et al. (p. 66):

$$(4)\qquad Y = a + 35.1\,(1 - .9^{x})(1 - .6^{y}),$$

where x is depth of topsoil and y is percentage of organic matter in the top 6 inches of soil.

The parameter "a" is a constant representing yield theoretically obtainable on subsoil.

Gross returns and costs per acre for each rotation are given in Pawson et al. for average topsoil depth and organic matter equal to 18 inches and 3.3%, respectively. Percentage of land in wheat under each rotation is also available. An important task was to incorporate the influence of state variables, topsoil and organic matter, into the net return structure of each rotation. Multiplication of (4) by the product of wheat price and the proportion of land in wheat provides a term which measures the effect of the state variables on returns, viz.,

$$(5) \qquad 35.1(1 - .9^{x})(1 - .6^{y})P_{w}u/100,$$

where P_w and u are the price of wheat and percentage of the land planted to wheat, respectively. Net returns for a given rotation are adjusted downward by subtracting out (5) with $x = 18$ and $y = 3.3$; then (5) is added back as an algebraic term to get an equation in x and y.

Let the net returns partitioned in this way be denoted

$$(6) \quad R(u;P_w) + uP_w(35.1)(1 - .9^{x})(1 - .6^{y})/100.$$

For each of the six "efficient" rotations selected, as described earlier, there is a unique value of u and a calculated value of $R(u;P_w)$ at a given wheat price. A quadratic function was fitted to these six data points to get an estimate of $R(u;P_w)$ with price at \$1.60 and \$1.20 in 1957–58 dollars (\$4.25 and \$3.20 in 1978 dollars). These two fitted equations serve as the empirical estimate of $G(u,x,y)$ in (1) and are of the general form,

$$(7) \quad b_0 + b_1u + b_2u^2 + cu(1 - .9^{x})(1 - .6^{y}).$$

Parameter values for the two different prices of wheat are given in table 1.

Fertilization rates, particularly nitrogen, are implicit in the function $R(u,P_w)$ given in (6) and increase directly with u, the percentage of land in wheat. Fertilization rates vary across the crop rotations, and consequently, change with the level of u. However, data were not available to permit fertilization rates to be made functions of the state variables, and this is recognized as an important limitation when the state variables are substantially depleted from existing levels, particularly in the one state variable model presented below.

Table 1. Parameters for the Net Return Equation

Wheat Price	b_0	b_1	b_2	c
(\$ 1957–58)				
1.60	5.41	.06635	−.001023	56.16
1.20	5.48	−.02453	−.001089	42.12

Note: These parameters and prices can be converted to a measure in 1978 dollars by multiplication by 2.66.

The two wheat prices of \$4.25 and \$3.20 in 1978 dollars probably bracket the most likely prices to prevail in the near future. During 1970–79, the average wheat price received by farmers in the United States was \$3.62, when calculated in constant dollars and measured in 1978 dollars. Therefore, \$4.25 might be viewed as a relatively high price based on recent experience, but average prices in Washington have frequently been higher than the U.S. average in recent years (40¢ in 1978).

The rotation data in Pawson et al. provide organic matter losses from a base of 3.3%, but this information is not adequate to estimate $h(u,x,y)$ in (3). A linear relationship between average annual changes in organic matter (percent) and the level of organic matter at the time of initial sampling is presented in figure 3 of Horner et al. (p. 10), which suggests that a linear first-order difference equation would describe the dynamics of soil organic matter. The average of annual changes over several years is a good estimate of year-to-year changes for a given level of organic matter because the changes are so small.

The following general relationship is postulated for soil organic matter changes in the top 6 inches of soil:

$$(8) \qquad y_{t+1} - y_t = \alpha(u) + \beta y_t, \ \beta < 0.$$

The constant term $\alpha(u)$ is dependent on the crop rotation; but within the decision model, the percentage of land in wheat, u, determines the crop rotation. The parameter β was estimated to equal -0.01 from the graph in figure 3 of Horner et al. Checks on the data suggested that β was quite stable across many rotations and approximately equal to -0.01.

The intercept $\alpha(u)$ in (8) was estimated for each of the selected six rotations from the information on annual changes in organic matter from a base of 3.3% given in Pawson et al., under the assumption that β equals -0.01. From (8), it is seen that

$$(9) \qquad \alpha(u) = y_{t+1} - (1 + \beta)y_t.$$

The information on individual rotations permits calculation of the right-hand side of (9) when $y_t = 3.3$. The six rotations gave six data points for u and $\alpha(u)$, to which a quadratic function was fitted. Using this equation for $\alpha(u)$ and (8) with $\beta = -0.01$ gave the following estimate:

$$(10) \quad h(u,x,y) = -.0452 + .857(10)^{-4}u + .478(10)^{-6}u^2 + .01y.$$

Notice that depth of topsoil, x, does not enter in (10) and $h(u,x,y)$ is defined as losses in organic matter.

Unfortunately, sufficient data or information from published work could not be found to estimate the influence of soil organic matter on erosion losses. Therefore, soil losses were estimated as a function of the decision variable u, independently of the state variables, which does not allow organic matter to reflect its favorable influence on soil structure and associated reduction in soil losses. Soil losses are given in Pawson et al. for each rotation, which provided six data points in association with the six selected rotations. A quadratic function was fitted on these data points to get

$$(11) \quad \phi(u,x,y) = .0025 + .000261u + .1286(10)^{-5}u^2,$$

which completes the empirical measurement task.

Analysis of the Model

Solution of the optimization problem in (1) to (3) results in a decision rule expressing the decision variable u as a function of the state variables x and y. An approximation to this decision rule was obtained by using the methodology presented in Burt and Cummings (1977). An exact solution can be obtained by application of nonlinear programming to the optimization problem (Burt and Cummings 1970). Probably the most practical method to get an exact solution to a problem of this dimension is with dynamic programming (Bellman).

The approximately optimal decision rule for the soil conservation application is a special case of solving equation (26) in Burt and Cummings (1977, p. 16); only one equation out of the pair given there is required because there is only one decision variable. A simple computer program was written to calculate the solution of the equation implied by the approximately optimal decision rule. Each state variable was started out at its lower bound and systematically incremented after a solution for the decision variable was obtained for a given pair of values of the state variables. This procedure generated the decision rule for the entire domain of the two state variables. Solutions were computed for a range of interest rates, too, but results reported here are for a 6% rate; the decision rule was quite stable for rates of 3% to 8%.

Under a wheat price of $4.25 per bushel in 1978 dollars, the decision rule is at its upper boundary of 85.7% wheat for nearly the entire domain of the state variables. This upper bound is continuous winter wheat with clean cultivation once in seven years. The only exception is at extremely low levels of organic matter, less than 1.5% if topsoil is 6 inches or more. In other words, when the topsoil is 6 inches deep or more and soil organic matter is 1.5% or more, 85.7% of the farm's cropland should be in wheat.

This intensive utilization of the land is not as exploitive as it might seem when the wheat is fertilized quite heavily with nitrogen, as is assumed in this model. Under this land utilization, equilibrium soil organic matter is about 3.5%, and annual soil losses are around 4.75 tons (.035 inches) per year. At this rate of soil loss, it would take twenty-eight or twenty-nine years to lose an inch of topsoil.

When wheat price is reduced to $3.20 per bushel in 1978 dollars, the decision rule is much more interesting, although this is a rather low price for wheat. The decision rule is summarized in figure 1, with contours on the decision rule surface. As would be expected, a small part of the farm is planted to wheat when soil organic matter is low simultaneously with a relatively shallow top soil, and vice versa.

In following the decision rule in figure 1 with 3% organic matter, it would take twenty-eight years to lose an inch of topsoil when its depth is now 18 inches, and it would take thirty-eight years to lose an inch if topsoil depth is only 7 inches. The decision rule puts 85.7% and 69% of the farm in wheat in these two respective states. Consequently, we see that the farm is heavily planted to wheat even with as low a price as $3.20 per bushel.

Following the computed decision rule will ultimately reduce the depth of topsoil to such a shallow layer that normal tillage operations will start mixing the subsoil into the existing topsoil and tend to dilute the organic matter

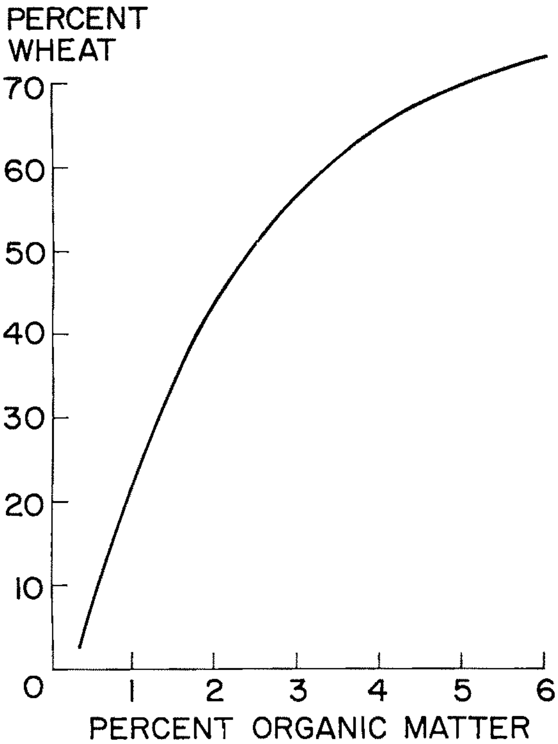

Figure 1. Decision rule with wheat at \$3.20 per bushel (percentage of land in wheat)

content. Average depth of topsoil in the study area was about 18 inches in 1960 (Pawson et al.), so it will take many more years to lose enough soil to create this situation where subsoil is mixed into the topsoil. A rough calculation suggests about 400 years to go from 18 to 6 inches of topsoil when following the decision rule for \$3.20 wheat, and about 330 years when following the rule for \$4.25 wheat. During a time span of this length, additional topsoil might be formed under this relatively intensive cropping system with wheat, but the model makes no allowance for new topsoil to be formed from beneath that already existing.

Nevertheless, a model which assumes a relatively shallow topsoil is of interest for farms and parts of farms where the topsoil is already thin. Many of the upper slopes of the hills have 6 inches or less of topsoil now.

A Single State Variable Model

A modified model is formulated under the assumption that the topsoil has eroded away and left only 6 inches. In addition, we assume that the tillage operations are to a depth of 6 inches, which incorporates new subsoil material into the layer of topsoil as soil is eroded away. Therefore, high soil losses make it more difficult to build up or increase soil organic matter in the top 6 inches.

The above model for two state variables can be reduced to a single state variable model by a simple relationship between $\phi(u,x,y)$ and $h(u,x,y)$. Because the topsoil will be kept at 6 inches depth by mixing subsoil with topsoil that is eroded away, the percentage of organic matter in year $t + 1$ is given by

$$(12) \quad y_{t+1} = y_t[6 - \phi(u_t,x_t,y_t)]/6 - h(u_t,x_t,y_t).$$

The term in square brackets expresses the dilution effect on organic matter of soil erosion losses.

The state variable x for depth of topsoil is set equal to 6 in (12), which gives a simplified difference equation for changes in the percentage of organic matter of the soil, namely,

$$(13) \qquad y_{t+1} = y_t - g(u_t,y_t),$$

with $g(u,y)$ defined as losses in organic matter during the year. The specific empirical relationship for (13) is obtained by substitution of (10) and (11) into (12) and rearranging the results to get the general form of (13). The expression for $g(u,y)$ is

$$(14) \quad g(u,y) = -.0452 + .857(10)^{-4}u + .478(10)^{-6}u^2 + [.01042 + .435(10)^{-4}u + .2143(10)^{-6}u^2]y.$$

The only modification in the annual net return function $G(u,x,y)$ is to set x equal to 6, which reduces the number of arguments to only two.

The approximately optimal decision rule of this model was calculated by the method given in Burt and Cummings (1977) and compared with the exact decision rule calculated by a dynamic programming algorithm. The dynamic programming algorithm was used with extremely precise accuracy to insure that any differences in the decision rules would be detected. The discrete intervals of approximation were 0.01 and 0.0001 for the state and decision variables, respectively; both are measured in units of percent. The dynamic programming algorithm also used linear interpolation for values between the discrete intervals.

The error in the approximately optimal decision rule was less than one-half of one percent of the optimal value of the decision variable (percentage of land in wheat) when the

state variable was in the interval between 1.0% and 6.0% organic matter. These results are for a 6% discount rate and a $3.20 wheat price in 1978 dollars. The error was somewhat larger when the state variable was less than 1.0; for example, the errors were 0.7% and 1.2% of the optimal value when soil organic matter was 0.9 and 0.8, respectively. But this largest percentage error for organic matter at 0.8 was only 0.2% of the land area in wheat in absolute terms, clearly trivial and meaningless in a practical sense.

We conclude that the approximately optimal decision rule is very accurate in this soil conservation application. Comparable results should be obtained in other dynamic optimization problems where the state variables change slowly and smoothly over time; in particular, good results should be typical for economic applications to soil conservation.

The optimal decision rule is given in the first two columns of table 2 and in figure 2. The equilibrium state for organic matter is 2.885% and the optimal percentage of land in wheat at the equilibrium state is 56. Annual soil losses would be 2.9 tons per acre in the equilibrium state, which implies an inch of soil loss about every forty-five years.

Table 2. Single State Variable Decision Rule and Marginal Values of Organic Matter

Organic Matter	Optimum Wheat Area	Marginal Value Organic Matter[a]
(%)	(%)	($ 1978)
0.50	8	45.03
0.75	16	53.14
1.00	23	57.72
1.25	29	59.75
1.50	35	59.93
1.75	40	58.89
2.00	44	56.97
2.25	48	54.52
2.50	51	51.48
2.75	54	48.41
3.00	57	45.19
3.25	59	42.04
3.50	61	38.92
3.75	63	35.91
4.00	65	33.07
4.25	66	30.39
4.50	68	27.85
4.75	69	25.48
5.00	70	23.30
5.25	71	21.24
5.50	72	19.37
5.75	72	17.65
6.00	73	16.12

Note: Wheat price in 1978 dollars was $3.20 and the discount rate was 6% in the analysis.

[a] Marginal discounted value of net returns associated with an increment to organic matter at the beginning of an infinite planning horizon.

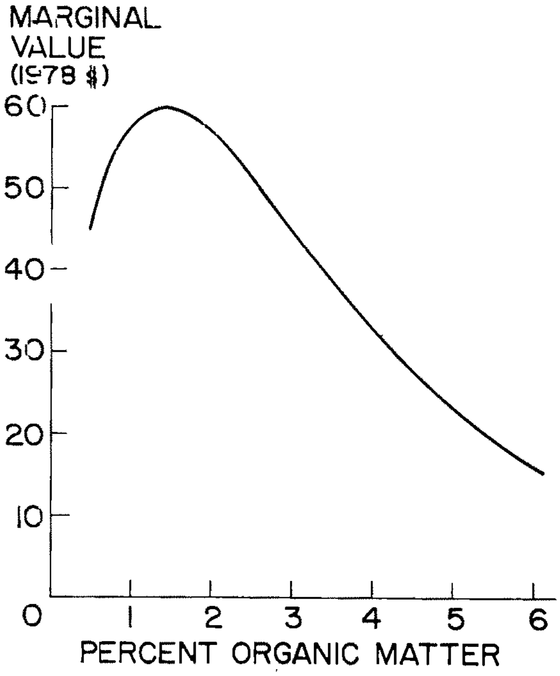

Figure 2. Decision rule with wheat at $3.20 per bushel

Marginal values associated with an increment to organic matter at the beginning of an infinite planning horizon are given in the last column of table 2 and are graphed in figure 3. These values would be the Lagrange multiplier in a Kuhn-Tucker theory framework (Burt and Cummings 1970) or continuous time-control theory model (Hadley and Kemp). In a dynamic programming model, these values are the slope of the functional equation (Burt and Cummings 1977, appendix).

Note how these marginal values first increase at low levels of organic matter, reach a maximum at about 1.5, and then decline monotonically. This is the same structure as the marginal curve to a classic physical productivity curve from the theory of the firm. These quite high marginal values illustrate the value of organic matter in a farming system, even though large amounts of inorganic nitrogen fertilizer are used.

When wheat price is increased to $4.25 per bushel in 1978 dollars, the decision rule hits the upper boundary of 85.7% wheat if organic matter is greater than or equal to 1.5%. Even at 1.0% organic matter, the optimal percentage of the farm to plant to wheat is 75. The equilib-

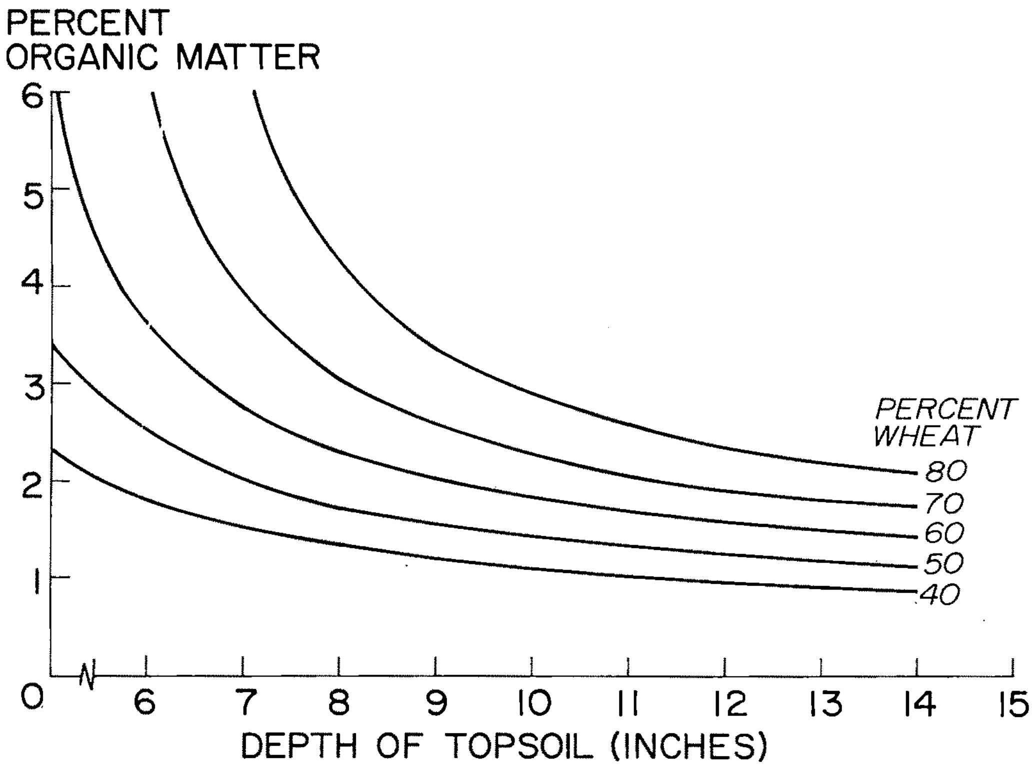

Figure 3. Marginal values of organic matter with wheat at $3.20 per bushel

rium state of organic matter is only 2.15% under the higher price, compared to 2.89% when the wheat price is $3.20. An inch of soil is lost about every twenty-eight years, and it is this relatively heavy soil loss in association with the dilution effect of the subsoil which depresses organic matter.

Concluding Remarks

The methodology of approximately optimal decision rules given in Burt and Cummings (1977) was shown here to be accurate in soil conservation decision models when the state and decision variables are continuous. The approximation methodology is based on a linear approximation to the functional equation of dynamic programming in the "neighborhood" of the equilibrium state. Apparently, this neighborhood in mathematical analysis is sufficiently large in empirical problems of conservation economics that it encompasses nearly the entire domain of the decision rule, only losing its accuracy as the state variables approach zero. This fortunate result stems from the slow changes in the state variables over time under an optimal decision rule in conjunction with discounting of net returns. The methodology is readily extended to stochastic models as well (Burt).

The results of this study demonstrate that relatively high grain prices exacerbate soil erosion problems, a proposition long held by economists writing on the economics of soil conservation (see Bunce and Ciriacy-Wantrup). Nevertheless, empirical results for the Palouse suggest that intensive wheat production with good cultural and fertilization practices is economically justified in the long run, as well as for immediate net returns. The extra losses of topsoil and organic matter, compared to more forage in the cropping system, are within economic limits and not a threat to long-run productivity of the soil. Problems are of a localized nature on the steepest slopes and hilltops, which should have a specialized cropping system applied insofar as it is feasible without creating too many technical inefficiencies on modern, large-scale farms.

Unless there is a substantial increase in the

price of forage relative to grain crops, it would appear that these conclusions would prevail in the foreseeable future. Although the analysis was done with what appears to be too low a relative price for alfalfa hay, technological change has substantially increased wheat yields, which probably more than compensates. The cultural practice of no-till farming combined with modern herbicides gives this conclusion even greater credibility.

These results for the Palouse cannot be extrapolated to other regions, such as the problem areas of southern Iowa and northern Missouri, for several reasons. First, climates are much different and row crops have their own unique hazards. Second, the deep loess soils of the Palouse are uncommon, and a shallow soil mantle is extremely vulnerable to soil losses which could ultimately destroy the water storage capacity of the soil. Third, gulleying from water erosion in some climates and soils is so serious that major investments in terraces are the only long-term solution if grains are to be a large part of the rotation.

Unfortunately, data are not available for comparable analyses in most regions, nor does it appear that the necessary measurements are being taken to produce a homogenous time series of observations. A critical set of data is that required to estimate the difference equations for soil losses and organic matter changes, i.e., (2) and (3), which characterize the dynamics of the problem. Also, considerable agronomic experimentation over an extended time horizon is needed to estimate yield responses to the state and decision variables, the basis of $G(u,x,y)$ in (1).

In view of rising energy costs and world population pressures, a comprehensive research program administered so that there is continuity in the process should be undertaken in the regions where soil erosion is a major threat. A minimum planning horizon for the research projects would be a decade, but reliable data to estimate the dynamics of organic matter changes would probably require annual measurements over a quarter-century. Current research that relates to these empirical measurement problems is almost always sporadic and without any continuity; consequently, the conditions under which the data are collected are not homogenous enough to provide reliable relationships among the variables.

A New Analytical Framework for the Fertilization Problem

Edgar A. Lanzer and Quirino Paris

A novel control model for technical and economic analysis of fertilizer recommendations is based on Liebig's Law of the Minimum, Mitscherlich's relative yield theory, and the notions of yield plateau and soil fertility carry-over. The empirical model consists of a multistage separable programming specification which maximizes the discounted stream of net revenues subject to crop response and fertility carry-over functions. The model is applied to the wheat-soybean cropping system in Southern Brazil. It is found that, while the optimal fertility target levels are within a small range of those determined by Brazilian agronomists, their maintenance recommendations could be substantially improved.

Key words: Brazil, crop response, fertility carry-over, nutrient nonsubstitution, optimal control, relative yield, yield plateau.

The analysis of yield response to fertilizers has been recently enriched by an original proposal of Cate and Nelson. These soil scientists suggested that for agronomic purposes and for certain crops, it may be convenient to postulate that the relationship between yield and major nutrients is a linear response and plateau (LRP) function. They argued that this simplified specification is nonetheless capable of capturing the essential information of yield response to nutrients such as potassium, phosphorus, and even nitrogen.

This interesting proposal has found little receptivity among agricultural economists who, as Perrin writes, "tend to think of the world as having smooth curves rather than corners" (p. 57). To date, Perrin's study seems to constitute the only economic analysis which utilized the LRP specification and compared it with the traditional polynomial response model. Perrin's conclusions are of great interest: "It will be surprising to some that the LRP provides recommendations as valuable on the average to farmers as those from the quadratic function. . . these particular results should serve to cast some doubt on the widespread (among economists) notion that fertilizer response should always be analyzed by fitting a smooth response surface" (pp. 59–60).

The proposal by Cate and Nelson seems relevant not only because it introduces explicitly the notion of plateau maximum ("a phenomenon that many agricultural economists have noted—that response curves often tend to be quite flat on top" [Perrin, p. 57]); but, more important, because it explicitly reintroduces into the response analysis the agronomic principle known as "the law of the minimum," formulated by von Liebig around 1850. This "law" states that "the yield of any crop is governed by any change in the quantity of the scarcest factor, called the minimum factor, and as the minimum factor is increased the yield will increase in proportion to the supply of that factor until another becomes the minimum. If another factor, not at the minimum, is increased or decreased, the yield would not be affected" (Redman and Allen, p. 454). Therefore, one fundamental implication of Liebig's principle is the absence (or the very limited possibility) of nutrient substitution. With the adoption by agricultural economists of the polynomial response model, the nonsubstitution hypothesis and the yield plateau were completely discarded from economic analyses.

In this paper, we propose a method for estimating response functions of the von Liebig type together with fertility carry-over relations. The LRP model of Cate and Nelson is

first modified into a piecewise linear and plateau model estimable by linear spline techniques. The relative yield theory of Mitscherlich, widely used by agronomists and soil scientists, is also incorporated into the model. Second, the single-nutrient responses are combined into a minimum function that is a generalization of the Leontief production function. Third, the estimated carry-over and response functions are assembled into an economic control model for optimal fertilizer recommendations, which takes the form of a multistage separable convex programming model. The model is finally applied to experimental Brazilian data featuring an eight-period, wheat-soybeans-cropping system.

The Yield-Nutrient Response Model

Abstracting from error terms, observed yields are known to be a function of many variables such as

$$(1)\qquad y = f(\mathbf{W}, \mathbf{S}, \mathbf{Z} \mid \mathbf{G}, \mathbf{O}),$$

where y stands for yield, **W** is a vector of weather variables; **S** is a vector of soil type variables such as percentage of clay content, pH, soil depth, moisture-holding capacity, redox potential; **Z** is the vector of total supply of macronutrients, that is $\mathbf{Z} = \mathbf{B} + \mathbf{X}$, where **B** is the vector of nutrients' natural supply already in the soil and **X** is the vector of fertilizer applications (the relationship of **B** to soil tests will be examined in the next section); **G** and **O** stand for vectors of genetic load and other factors (such as planting density, for example) which are assumed to condition the yield-nutrient relationship.

Although a simplification of reality, relation (1) is yet too general both for deriving testable hypotheses and for practical implementation of fertilizer recommendations. Many agronomists, for example, have followed Mitscherlich's original suggestion contained in the "principle of relative yields." It was Bray (1954, 1958, 1963), however, who provided a full explanation of the principle as well as of the conditions for its validity. Assuming only one variable nutrient, for the moment, the principle of relative yields postulates that (1) can be respecified as

$$(2)\qquad y = A \cdot g(b + x \mid \mathbf{G}, \mathbf{O}),$$

where A is a parameter representing the maximum attainable yield given some levels of weather and soil variables, **W** and **S**, $g(\cdot)$ is a function called "relative yield response," b represents the nutrient's level already in the soil, and x is the corresponding application. As Mitscherlich postulated it, this function does not depend on weather and soil variables. From the definition of A, the maximum yield attainable given **W** and **S**, the function $g(\cdot)$ varies between zero and one; hence, its name of relative yield function.

According to Bray (1954, 1958, 1963), relation (2) would be valid only for the so-called immobile nutrients, such as phosphorus and potassium. Nevertheless, Hildreth found no significant interaction between soil type, weather, and nitrogen levels when corn yields were expressed in logarithms in a discrete response model fitted to a large set of experimental data. He states (p. 68) that this result "confirmed the a priori belief that equal percentage effects were a more plausible assumption than equal absolute effects." The principle of relative yields may thus have a practical validity even beyond the conditions prescribed by Bray. In any event, the principle is an important tool employed by soil scientists for the design of fertilizer recommendations (see Rouse).

The relative yield theory proposed by Mitscherlich and described by (2) contains an implicit assumption about separability of weather and soil type variables, on one hand, and nutrients on the other. Suppose, in fact, that the general yield-nutrient relationship can be represented adequately by a weakly separable function with respect to the partition (set of weather and soil type variables, set of nutrients), such as

$$(3)\qquad y = h(\mathbf{W}, \mathbf{S})g(b + x \mid \mathbf{G}, \mathbf{O}).$$

It is now evident that Mitscherlich's maximum yield parameter A, when measured in crop experiments, is a function of given levels of weather and soil type variables. Hence, by combining (2) and (3), we conclude that a more explicit formulation of the relative yield model is

$$(4)\qquad y = A_{ws}g(b + x \mid \mathbf{G}, \mathbf{O}),$$

where A_{ws} is now a location parameter measuring the yield plateau of a given experiment. The practical and relevant consequence of the weak separability assumption stated in (4) is to provide a simple and powerful criterion for pooling experimental data of different years and soil classes. This conclusion is supported

by the empirical results discussed later. In this context, therefore, the location index A_{ws} estimates the yield plateau of a given experiment conducted with weather conditions **W** in a soil class **S**. Furthermore, reliable estimates of A_{ws} are not difficult to obtain in view of the general shape of the yield response postulated by some soil scientists and illustrated in figure 1. This figure was reproduced from a widely adopted textbook of soil science (Russell, p. 49). It exhibits a yield response curve with a plateau maximum rather than a point maximum. The interval (k_1, k_2) in figure 1 is considered to be quite wide for macronutrients such as nitrogen, phosphorus, and potassium (Corey and Schulte, p. 31). The notion of a plateau maximum yield, A, is consistently found in the functions proposed by several soil scientists such as Mitscherlich: $y = A[1 - \exp(-c(b + x))]$, Balmukand: $y^{-1} = A^{-1} + c(b + x)^{-1}$, and, more recently, Cate and Nelson: $y = \text{Min}[A, c(b + x)]$.

The formalization of the yield-nutrient relationship involving two or more nutrients follows von Liebig's "law of the minimum," according to which macronutrients cannot substitute for each other (or the substitution region is very limited). Barber is quite explicit in this regard: "economists . . . have pointed out that when crops are fertilized to a certain yield level, there are a number of different combinations that will give the same yield . . . but since P cannot substitute for K in the plant, any substitution must be small in amount" (p. 210). Tisdale and Nelson, too, assert that "the substitution concept is not a sound long-time

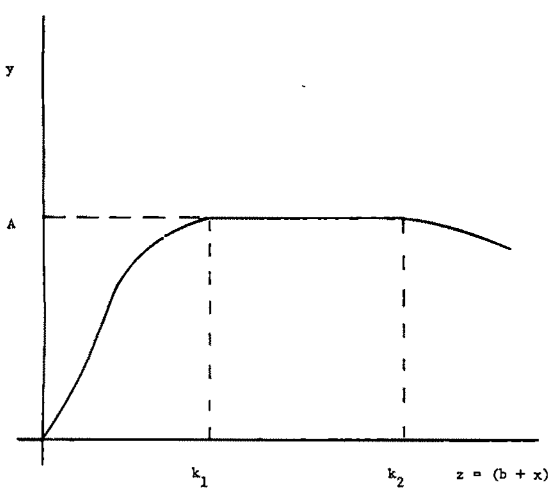

Figure 1. Yield response (y) to total supply of variable nutrient (z)

approach" (p. 618). Hence, combining the proposals of several agronomists (see also Waggoner and Norvell), we postulate the following multinutrient response function:

$$y = A_{ws} \min_{i \in I} [g_i(b_i + x_i)], \tag{5}$$

where I is the set of macronutrients—nitrogen (N), phosphorus (P), potassium (K)—and the other symbols are as before. The conditioning factors **G** and **O** are omitted for convenience. The relative yield functions $g_i(\cdot)$ are, in general, nonlinear and therefore, model (5) is an extension of the well-known Leontief production function with fixed input-output coefficients.

Fertility Carry-Over

The specification of the fertilization model must be completed with the discussion of the fertility carry-over problem. This is because "as fertilizer is applied in increasing quantities, it becomes apparent that increased attention must be given to the value of carry-over. In many cases the cost of fertilization is charged to the crop treated. However, carry-over fertilizer is like money in the bank and is part of fertilizer economics. Hence, it is apparent that if we are to make a critical evaluation of fertilizer use, the carry-over value must be considered" (Tisdale and Nelson, p. 538). Although agricultural economists have written only a few papers on this subject (Kennedy et al.; Stauber, Burt, Linse; Fuller), the above quotation clearly indicates the importance that agronomists attribute to fertility carry-over. In fact, fertilizer recommendations made by soil scientists seek to build and to maintain the level of soil fertility at the minimum level required to achieve the yield plateau (Rouse, p. 16–17). But how is soil fertility to be measured?—by means of soil tests. Agronomists consider a clear understanding of soil test measurements to be of fundamental importance for the design of fertilizer recommendations. This is because, in many instances, most of the available information concerning a particular farming site comes embodied into a single soil sample. It is from the chemical analysis of such a small piece of information that fertilizer recommendations are to be made. In the terminology of optimal control theory, soil test measurements are "sensor measurement signals" of a dynamic stochastic process (Athans). Soil-testing

chemical methods, on the other hand, constitute the sensors themselves. Ideally, the soil sensors should produce measurements expressed in the same units employed to measure fertilizer quantities, irrespective of everything else. However, such an idealized set of sensors has not yet been produced by soil scientists.

Therefore, the quantity b of a given nutrient available in the soil is to be measured by soil tests, b^*, which soil scientists assume to be proportional to the true values of b. In other words, $b = \lambda b^*$, where λ is a proportionality factor. The condition required for the validity of the above assumption is that the chemical form of the nutrient in the soil be constant (Bray 1954, 1958, 1963). However, such chemical forms vary somewhat with soil type. The pragmatic approach followed by soil scientists, then, is to classify soils into homogenous groups according to their λ values and, since the λ's are specific of each nutrient, a classification of soils in terms of λ for potassium may be different from a classification of the same soils made on the basis of λ for phosphorus. Soil scientists suggest that estimates of λ for a given nutrient i can be obtained from the following simple formula:

$$\lambda_i = x_i/(b^*_{it} - b^*_{io}), \tag{6}$$

where b^*_{io} is a soil test measurement for the ith nutrient prior to a fertilizer application of x_i units of the same element, and b^*_{it} is a soil test measurement made before the next crop. Since one of the explicit goals of fertilization is that of building up the fertility levels in the soil, b^*_{it} is greater than b^*_{io} and, therefore, $\lambda_i > 0$. In conclusion, since the λ coefficients are known to vary with soil type, model (5) incorporating soil test measurements becomes

$$y = A_{ws} \operatorname*{Min}_{i\epsilon I} [g_i(\lambda_{is}b^*_i + x_i)]. \tag{7}$$

The above discussion, while concentrating on the interpretation of soil test measurements, also makes clear the necessity for casting the problem of making fertilizer recommendations into a dynamic framework. From the point of view of the soil laboratory that makes such recommendations, the control problem of achieving and maintaining the fertility stock at any desired level requires updated estimates of the level of extractable nutrients in the soil. Those estimates do not necessarily require the knowledge of past fertilizer applications, yields, and weather conditions (although these may help in some cases). Instead, updated estimates of the level of extractable nutrients in the soil are to be obtained from the chemical analysis of soil samples. Thus, the dynamic extension of the yield-nutrient response model incorporates fertility carry-over equations, which are specified in terms of (a) the state variables that can be observed, i.e., soil test measurements, and (b) the decision variables that may affect the level of the state variables, i.e., fertilizer applications. The equations of motion describing the transfer of fertility in the soil from period to period are, therefore, specified as

$$b^*_{it} = h_i(b^*_{it-1} + \lambda_{is}^{-1} x_{it-1}), i\epsilon I, \tag{8}$$

where b^*_{it} is the soil test result for the ith nutrient at the beginning of period t, and x_{it-1} is the quantity of the ith nutrient applied as fertilizer in period $t - 1$. Notice that while the term $(\lambda_{is}b^*_i + x_i)$ in (7) represents the total supply of the ith nutrient as measured in fertilizer units (e.g., pounds of P_2O_5 per acre), the term $(b^*_i + \lambda_{is}^{-1}x_i)$ in (8) represents the total supply of the ith nutrient as measured in soil test units (e.g., ppm of P). Equations (7) and (8) constitute the model of yield-nutrient response which can be called the dynamic relative-yield-nonsubstitution model. To estimate the yield response function (7), one needs to know the parameters λ_{is}, which, in turn, are obtained from the estimation of the fertility carry-over equations (8).

Economic Analysis of Fertilizer Recommendations

The principal objective of the approach proposed in this study is to evaluate the appropriateness of the fertilizer recommendations provided to farmers by extension agents. Typically, such recommendations are obtained from tables constructed by soil scientists who classify the soils of a given region and determine the "appropriate" fertilizer's build-up and maintenance doses. In general, these tables do not reflect possible variations of the economic environment.

In order to verify the adequacy of these tables, we postulate that farmer's objective is to maximize the discounted stream of net revenues subject to the yield response and fertility carry-over model (7) and (8) described in previous sections. Symbolically, and for a

planning horizon of T periods, such a model can be represented as

$$(9)\quad \text{Max } \pi = \sum_{t\epsilon T} (1 + r)^{-t} \left(P_y \cdot A \cdot g_t - \sum_{i\epsilon I} P_i x_{it}\right)$$

$$\text{subject to } g_t - g_i(\lambda_{is} b^*_{it} + x_{it}) \leq 0.$$

$$b^*_{it} - h_i(b^*_{it-1} + \lambda_{is}^{-1} x_{it-1}) = 0,$$

$$b^*_{i1} = \text{given, } x_{it} \geq 0,\ i\epsilon I,\ t\epsilon T,$$

where P_y is the output price, P_i is fertilizer prices, r is the interest rate, and other symbols are as before. The b^*_{i1} initial conditions represent known soil test levels at the beginning of the planning horizon T. For simplicity, inputs other than fertilizers are not included in (9), but it would not be difficult to adapt the model for their inclusion. Also notice that, once the maximum yield parameter A is known (through experimental data or agronomists' suggestions), function (7) can be rewritten as a relative yield function $g_t = y/A = \min [g_i(\lambda_{is} b^*_{it} + x_{it})]$ or, equivalently and more operationally, as max g_t subject to $g_t - g_i(\lambda_{is} b^*_{it} + x_{it}) \leq 0$, i = N,P,K and $t\epsilon T$. This last reformulation is used in model (9).

The exogenous information of model (9) is represented by output and input prices, the discount rate, the crop's maximum yield A, the estimates of the relative yield response and fertility carry-over functions, and the initial levels of soil fertility. The endogenous information obtained by solving model (9) is constituted by the optimal fertility targets, b^*_{it}, $i\epsilon I$, $t\epsilon T$, $t \neq 1$, and the optimal fertilizer applications, x_{it}. The fertilization strategy so derived is obviously dependent upon the initial soil test levels. Furthermore, farmers periodically acquire new information on fertility levels by means of soil tests. They can, and probably do, use this information for updating their fertilization strategy. A conceptual modification of the problem is then required to accommodate this situation. The incorporation of the updating information into the programming formulation can be achieved by the "moving horizon" concept. Under this concept, "every decision made is a first-period decision with a (finite) horizon" (Theil, p. 155). The control rules obtained from model (9) can be summarized as follows: for a given expected yield plateau and a given set of expected prices, there will be an optimum stock of soil fertility to be maintained by means of periodic supply of fertilizer inputs. The stock of soil fertility present at any given point in time is measured via soil tests. The optimum quantity of fertilizer (control) to apply in any given period will be the difference between the current soil fertility level and its desired stock level (target). In this framework, knowledge of the carry-over functions are all that is necessary to exert control over the system once soil test targets are provided by the solution of (9).

Lastly, notice that if the carry-over functions in (9) are concave, then the set of feasible solutions remain convex and a separable programming version of (9) can be solved directly with conventional linear programming techniques.

Application to Wheat-Soybeans in Southern Brazil

The discussion in previous sections was centered around the design of a model representing yield-fertilizer relationships incorporating agronomic principles and procedures. This section reports the results of an application of that model to evaluate the economics of fertilizer recommendations currently made for the wheat-soybeans double-croping system in Southern Brazil. The data available for the empirical research gathered from thirty-eight different experiments precluded the joint estimation of all yield responses and carry-over functions. Linear carry-over functions were estimated for phosphorus and for potassium under the assumption of a geometrically declining process and of an autoregressive error term. The estimation of carry-over functions generated estimates of λ coefficients, which, in turn, were used to compute total availability of nutrients from the knowledge of soil test levels and fertilizer application for each observation. Constrained linear spline regression techniques were used to estimate the wheat and the soybean responses to total phosphorus and to total potassium. Splines equations were constrained to attain a maximum of 1, or 100%, at, or before, a certain level of supply of the variable nutrient; this level was considered sufficiently high to attain the yield plateau according to the experience and suggestion of Brazilian agronomists. Data from different sites and years were pooled under the principle of relative yields. To do so, a proportion of the maximum observed yield at each experiment was used as a proxy for the expected

yield plateau of that experiment. Such proportion was estimated within the regression framework.

Wheat response to nitrogen was estimated directly under the specification of a Mitscherlich type function (organic matter content being used as a proxy for the level of soil nitrogen; carry-over nitrogen is considered to be insignificant in the context of wheat-soybeans in Southern Brazil). A nonlinear Gauss-Newton procedure was used to estimate all carry-over and yield response functions. This procedure allowed for (*a*) the direct estimation of the parameters of carry-over equations including the autoregression coefficient and (*b*) constraining the parameters of the spline in order to ensure quasi-concavity. In Southern Brazil, wheat and soybeans are grown in succession year after year with each crop occupying the land for roughly six months. Thus, the unit of time used in the analysis is half a year.

The results were as follows.

Carry-Over Functions

The econometric specification adopted for the carry-over functions of phosphorus and potassium was the following Koyck distributed lag specification.

$$(10)\quad b^*_{it} = \Theta_i(b^*_{it-1} + \lambda_i^{-1}x_{it-1}) + u_{it},$$

where b^*_{it} $(i = P,K)$ is the soil test level of the ith nutrient at the beginning of period t, Θ_i is a rate of geometric decline and $u_{it} = \rho_i u_{it-1} + e_{it}$, where e_{it} is a white-noise Gaussian error term. Lagging (10) one period, multiplying by ρ_i, and substracting from (10), one arrives at

$$(11)\quad b^*_{it} = \rho_i b^*_{it-1} + \Theta_i(b^*_{it-1} - \rho_i b^*_{it-2}) + \Theta_i\lambda_i^{-1}(x_{it-1} - \rho_i x_{it-2}) + e_{it}.$$

The parameters of (11) were directly estimated with a nonlinear regression procedure. The results are shown in table 1. For the case of phosphorus, a slight modification of (11) was adopted because data from two different soil types were pooled for the following reason. Local soil scientists believe that the λ^{-1} coefficient for P in one soil type (clay soils) is half the value as for other soil types. Hence, this information was entered in (11) with the help of a dummy variable for soil type. Two observations are in order with respect to the results shown in table 1. First, the estimates of the geometric decline coefficients for both P and K are relatively close to the unity. This means that fertilizer carry-over is highly significant for both nutrients in soils of Southern Brazil. Second, from the estimates of the λ_i^{-1} $(i = P,K)$, one concludes that, upon taking the inverse of such coefficients, (*a*) each ppm unit of P in a soil test for a clay soil is equivalent to an application of 48.26 kilograms of P_2O_5 per hectare on clay soils (this value reduces to 24.13 for other soils), and (*b*) each ppm unit of K on a soil test for all soils is equivalent to an application of 3.73 kilograms of K_2O per hectare. In the case of phosphorus, an unconstrained model was also fitted to the data. The estimates in this case were $\lambda_p = 51.69$ for clay soils and 22.80 for other soils.

Table 1. Carry-Over Estimates for Phosphorus and Potassium in Southern Brazil

[c] For clay soils; for other soils multiply the estimate by two.

Yield Response Functions

Once the estimates of the λ coefficients were available from the estimation of the carry-over functions, the total supply of phosphorus and potassium (z_P and z_K) were computed for each observation according to $z_i = \hat{\lambda}_{is}b^*_i + x_i$, $(i = P,K)$. Data used for the estimation of a yield response to any nutrient included only the observations for which the experience of local soil scientists indicated that the level of other nutrients was nonlimiting (i.e., within the range k_1, k_2 in fig. 1). To represent algebraically the yield response function we chose a linear spline specification for the following two reasons. First, it is a natural extension of the linear response and plateau model of Cate and Nelson, and explored by Perrin. Second, it allows greater flexibility of functional form

and does not impose any substitution requirement as, for example, the polynomial specification. The linear spline specification used in all cases (except for wheat response to nitrogen) was as follows:

$$(12) \quad y_{ne} = \alpha M_e \sum_{m=1}^{m=6} \beta_m V_{mne} + u_{ne},$$

where y_{pe} is yield (kg./ha.) observed on the nth plot of the eth experiment, M_e is the maximum observed yield of the eth experiment (notice that αM_e is used as proxy for the expected yield plateau of the eth experiment A_e) and where $V_{1ne} = z_{ne}$, $V_{2pe} = \text{Max}(L_1 - z_{ne}: 0)$, $V_{3ne} = \text{Max}(L_2 - z_{ne}: 0)$, etc., according to the requirements of the linear spline specification. The fixed knots L_m were chosen as middle points of classes of soil test levels currently adopted in fertilizer recommendation tables in Southern Brazil (the last knot, L_5, was located beyond the level that soil scientists consider sufficient to attain the yield plateau). The relative yield function represented by the spline formulation was postulated to attain its maximum of unity (100%) for some range of z starting at L_m $(m < 5)$ and extending to L_5 at least. Under this constraint, the spline should satisfy:

$$(13) \quad \beta_1 L_1 + (\beta_1 + \beta_2)(L_2 - L_1) + (\beta_1 + \beta_2 + \beta_3)(L_3 - L_2) + \ldots + (\beta_1 + \beta_2 + \ldots + \beta_5)(L_5 - L_4) = 1,$$

or, upon simple algebraic manipulations of (13):

$$(14) \quad \beta_1 = L_5^{-1} - (L_5 - L_1)L_5^{-1}\beta_2 + (L_5 - L_2)L_5^{-1}\beta_3 - \ldots - (L_5 - L_4)L_5^{-1}\beta_5.$$

Equation (14) represents a linear constraint upon the parameters of the linear spline formulation of the yield response. By substituting (14) into (12) and rearranging terms one arrives at

$$(15) \quad y_{ne} = \alpha R_{1ne} + \alpha\beta_2 R_{2ne} + \ldots + \alpha\beta_5 R_{5ne} + \alpha\beta_6 R_{6ne} + u_{ne},$$

where $R_{1ne} = M_e L_5^{-1}$, $R_{2ne} = M_e[V_{2ne} - (L_5 - L_1)L_5^{-1}V_{1ne}]$, $R_{3ne} = M_e[V_{3ne} - (L_5 - L_2)L_5^{-1}V_{1ne}]$, etc. The parameters of (15) were estimated by a Gauss-Newton algorithm, which further allowed constraining the β_m $(m > 2)$ estimates to be nonpositive (a requirement to ensure concavity of the estimated spline except for an initial range where increasing returns could occur). Parameter β_1 was recovered with the help of equation (14). The statistical results of the estimations of the responses of wheat and of soybeans to total supply of phosphorus and of potassium are summarized in table 2. The information of this table allowed for the computation of the estimates of knots in the spline formulation of the

[c] Computed according to equation (14).

relative yield responses. These estimates are presented in table 3.

For two reasons, the estimation of wheat response to nitrogen did not follow the same methods employed for phosphorus and potassium. First, the soil test for nitrogen is not a direct measurement of nutrient as in the case of P and K. Instead, nitrogen supply of the soil is indirectly evaluated through the organic matter percentage content of the soil. Second, nitrogen carry-over is not important within the context of wheat-soybeans in Southern Brazil: soybeans produce their own nitrogen via Rhizobium bacteria and rainfall leaches fertilizer nitrogen very rapidly in that region. Therefore, it was decided to estimate the relation between soil nitrogen, applied nitrogen and yields directly via the yield response function. The model adopted in this case was a Mitscherlich type function:

(16)

$$y_{ne} = \alpha M_e[1 - \exp(c^* b^*_{Nne} + c\, x_{Nne})] + u_{ne},$$

where y_{ne} is observed yield of the nth plot of the eth experiment, M_e is the maximum observed yield at the eth experiment, b^*_{Nne} is the soil test level for percentage organic matter of observation n, e, and x_{Nne} is fertilizer nitrogen applied on the nth plot of the eth experiment (in kg. of N per ha.). Notice that, in (16) the term within brackets is relative yield response to total nitrogen. This, in turn, is defined as $z_N = \lambda_N b^*_N + x_N$, where, in view of (16), $\lambda_n = c^*/c$. Table 4 reports the statistical results obtained with model (16).

From the estimates of c^* and of c, one gets

c	−0.0429	0.02990

Note: There were 158 observations; R^2 = 0.8823.
[a] According to equation (16) in the test.

λ_N = 13.13, i.e., each percentage unit of organic matter is estimated to be equivalent to an application of 13.13 kilograms of N per hectare. In the multiperiod LP model, the continuous function estimated for N was approximated as a convex combination of the following levels of total nitrogen supply: 0, 30, 60, 90, and 120 kilograms of N per hectare.

At this point, all the physical components of problem (9) had been estimated, except for the expected yield plateaus for wheat and for soybeans. According to agronomists of the National Wheat Research Center (CNPT), the expected yield plateaus for wheat and for soybeans at the farm level in Southern Brazil are 1800 kilograms per hectare and 2800 kilograms per hectare, respectively. The prices used in the programming model were (Cr$/kg) 5.61 for N, 7.06 for P_2O_5, 2.49 for K_2O, 2.03 for wheat, and 1.84 for soybeans. They are average prices during 1976 for Southern Brazil. An interest rate of 3% per semester has been used to discount future cash flows. A planning horizon of four years (eight cropping periods: wheat, soybeans, wheat, etc.) was assumed for the purpose of the economic analysis.

The results of the analysis with the programming model were as follows:

(*a*) optimum soil fertility targets for wheat:
z_N = 57.15 kg. of N/ha. (or 4.35% organic matter content),
z_P = 375.0 kg. of P_2O_5/ha. (or 7.8 ppm of P for clay soils; 15.6 for other soils),
z_K = 202.6 kg. of K_2O/ha. (or 54.3 ppm of K);

(*b*) optimum soil fertility targets for soybeans:
z_P = 456.0 kg. of P_2O_5/ha. (or 9.4 ppm of P for clay soils; 18.8 for other soils),
z_K = 260.0 kg. of K_2O/ha. (or 69.7 ppm of K).

Input prices were also parameterized within the interval of 0.6 to 1.4 times the average prices used in the analysis. The conclusion was that the results found under average

prices were stable, particularly with respect to increases in input prices.

In view of these results, the analysis turned to a critical evaluation of fertilizer recommendations currently made by the agronomists for the wheat-soybeans double-cropping system. Such recommendations do not make a distinction between soil fertility targets for wheat and for soybeans. In either case soil scientists recommend that a level of 9 ppm of P (for clay soils; twice as much for other soils) and a level of 60 ppm of K be maintained in the soil (see UFRGS). Thus, only minor differences between the current recommendations and the computed optimum are detected as far as target levels for soil fertility are concerned (the differences are all in the range of 5% to 15%). Thus, in the analysis that follows, target levels for P and K currently suggested by Brazilian soil scientists will be regarded as optimal recommendations.

In order to maintain the levels of soil fertility at their desired targets, the Southern Brazilian agronomists recommend fertilizer applications of 75 kilograms of P_2O_5 per hectare per cropping period and 40 kilograms of K_2O per hectare per cropping period. Such recommendations can be evaluated through the carry-over equations [see equation (10) and table 3]. Taking the case of phosphorus first, letting $b^*_{Pt-1} = b^*_{Pt} = \beta^*_P$ (where β^*_P is thus defined as the desired target level for P in ppm units of P) and solving for $x_{Pt-1} = \chi_P$ (where χ_P is thus defined as the maintenance application of P in terms of P_2O_5 per hectare per cropping period), one finds that the estimated fertilizer application required to maintain the level of soil phosphorus at any desired level β^*_P is given by $\chi_P = 5.996\ \beta^*_P$ for clay soils and $\chi_P = 2.998\ \beta^*_P$ for other soils. Similarly, for the case of potassium, by letting $b^*_{Kt-1} = b^*_{Kt} = \beta^*_K$ (where β^*_K is thus defined as the desired target for K in ppm units) and solving for $x_{Kt-1} = \chi_K$ (where χ_K is thus defined as the maintenance application of K in kg. of K_2O per ha. per cropping period), one finds that the fertilizer application required to maintain the level of soil K at its desired soil test level is given by $\chi_K = 0.853\ \beta^*_K$. Soil test targets currently adopted by Southern Brazilian agronomists are $\beta^*_P = 9$ ppm of P (for clay soils; twice as much for other soils) and $\beta^*_K = 60$ ppm of K (for all soils). By substituting these values into the equations for χ_P and χ_K just derived, one finds that the maintenance applications levels for P and K should be approximately 54 kilograms of P_2O_5 per hectare per cropping period and 51.2 kilograms of K_2O per hectare per cropping period. These levels contrast with the maintenance levels currently adopted in Southern Brazil: 75 kilograms of P_2O_5 per hectare per cropping period and 40 kilograms of K_2O per hectare per cropping period. In short, even though the target levels are close to the computed optima (relative differences here were found to be in the range of 5% to 15%), it is clear that major modifications of maintenance fertilizer recommendations are in order (the relative differences found here are in the range of 30% to 50%).

The analysis above was centered in the cases of P and K. For nitrogen it has been found that current recommendations should be diminished from 10% to 50%, the difference increasing with increases in the level of organic matter content of the soil. Table 5 gives an overview of costs of alternative fertilization strategies, i.e., current recommendations versus recommendations derived in this research.

Table 5. Yearly Fertilization Costs Required to Maintain Soil Fertility at Desired Targets for Wheat-Soybeans Double-Cropping System (Southern Brazil, 1976 Prices)

	Current Recommendation		Suggested Recommendation	
Item	Quantity[a]	Cost[b]	Quantity[a]	Cost[b]
Maintenance N for wheat[c]	30.0	168.30	20.0	112.20
Maintenance P for wheat	75.0	529.50	55.0	388.30
Maintenance K for wheat	40.0	99.60	50.0	124.50
Maintenance P for soybeans	75.0	529.50	55.0	388.30
Maintenance K for soybeans	40.0	99.60	50.0	124.50
Total cost		1,426.50		1,137.80

[a] in kg. of N/ha. kg. of P_2O_5/ha. and kg. of P_2O_5/ha. for N, D, K, respectively.
[b] in Cr.$/ha.
[c] assuming a 3% organic matter content.

Notice that since both alternatives assume the same fertility targets, no significant change in output is likely to occur. Thus, the gains from the adoption of the recommendations derived in this study would come from a reduction in fertilizer costs. This reduction was estimated at Cr$ 288 per hectare per year, or US$27.30 per hectare per year (July 1976 exchange rate). The relative decrease in yearly fertilization costs would be around 20%, a significant amount.

Conclusions

This paper contains the suggestion of a model for examining fertilizer recommendations that incorporates soil science principles in a rather explicit manner. The use of this model in a practical setting helped to identify significant economic inefficiencies in the case studied. The model depends on several hypotheses adopted in soil science theory. Some of these hypotheses (such as the linear response and plateau) have been examined recently by Perrin with results not inferior to more conventional polynomial specifications.

Although further research effort is certainly warranted on all aspects of the fertilization problem, it seems possible to conclude that the dynamic relative-yield-nonsubstitution model presented here has performed satisfactorily in the wheat-soybeans environment of Southern Brazil. It has indicated that, as hypothesized, fertility carry-over is indeed significant for phosphorus and potassium. As to the dispute among agricultural economists about whether or not the traditional analysis of the fertilizer problem (based upon a polynomial specification of the response function and little concern for carry-over) is adequate, it seems appropriate to quote T. D. Wallace, who wrote: "statistical procedures substitute rather poorly for rigorous modeling based on the foundations of the field of application" (p. 443). The traditional polynomial form of the response function, so far preferred by agricultural economists, was suggested mainly because of its "good" fit. But, as was shown by Perrin and in this study, similar or better fits can be obtained with other functional forms which have the additional advantage of explicitly incorporating agronomic principles. This last point is important for two reasons. First of all, it follows T. D. Wallace's recommendation. Second, it allows a direct dialogue with many agronomists and soil scientists who conduct their fertilizer research on the basis of nutrient nonsubstitution, yield plateau principle, relative yield theory, and the notion of fertility carry-over.

An Economic Analysis of Expenditures on Agricultural Experiment Station Research

Wallace E. Huffman and John A. Miranowski

Experiment station research expenditures are responsive to economic and institutional forces. A four-equation model of resources allocation to state agricultural experiment station research, consisting of demand and supply equations for research, an equation allocating state governmental revenues to station research, and an expenditure identity, is presented. A reduced-form expenditure equation, derived from this model, is fitted to cross-sectional data for forty-eight U.S. states, pooled together for 1960, 1965, and 1970. A large share of the variance in per capita expenditures of state agricultural experiment stations is explained by the variables included in the model.

Key words: experiment station research, indigenous applied research, reduced-form expenditure equation, resource allocation.

The last decade can be characterized by a growing skepticism of the agricultural research establishment. Some have argued that agricultural researchers have been captured by the interests of large farmers or by large, private, farm-input supply firms (e.g., Hightower). Others have argued that the agricultural research establishment has been unresponsive to human resource, environmental, and income distributional issues (e.g., Mayer and Mayer). Some of these concerns have been expressed in recent changes made in the type of federal support for agricultural research.

The primary sources of funds available to state agricultural experiment stations have been federal funds appropriated on a formula basis and funds appropriated for agricultural research by state governments. Although formula funds are granted to the states on a matching basis, nonfederal support of research, which is largely state appropriations, has been at a level that substantially exceeds the federal matching rate in all states. In recent years, state appropriations for research have averaged about 60% of the total funds for state agricultural experiment station research (U.S. Department of Agriculture 1969). The U.S. Congress recently has established a federally funded competitive research grant program for agricultural research open to all scientists, those at both public and private institutions. Also, the Administration attempted in 1977–78 to substitute competitive grant funds for formula funds. These changes have caused a reassessment by the directors of the state agricultural experiment stations of their funding base.

Only a few studies have attempted an analysis of expenditures on agricultural experiment station research. Schultz (1971) first explicitly recognized the potential economic significance of disparities in funding state experiment stations. Hayami and Ruttan have argued for an economic analysis of public institutions involved in economic growth and development. Peterson attempted to identify through regression analysis a few factors that influence the allocation of funds to agricultural research. In his simple model, state nonfarm income emerges as the most important variable explaining total funds available to experiment stations. (See also Schultz, 1956; Heady; Peterson and Hayami.) In the first attempt to model the determination of agricultural research expenditures, Guttman applies a theory of public interest groups. The interest group

Journal Paper No. J-9773 of the Iowa Agriculture and Home Economics Experiment Station, Project 2198.

The authors received helpful comments on an earlier draft of this paper from T. W. Schultz, D. Gale Johnson, Ed Schuh, Vernon Ruttan, Yoav Kislev, W. Enders, Willis Peterson, Jim Hildreth, Roy Gardner, and anonymous referees. Also, they benefitted from presentation of an earlier draft in the Agricultural Economics Workshop, The University of Chicago, and at a seminar of the Department of Agricultural and Resource Economics, Oregon State University, and from discussion of this subject with Lee Kolmer and John Mahlstede.

purchases policies that are favorable to its members, in this case agricultural research, in exchange for support (votes and funds) for candidates for public office favoring policies sought by the group. In applying the model to cross-sectional expenditures on poultry, grain, and dairy research in 1969, research expenditures are explained by a limited set of variables hypothesized to affect the demand for research. The analysis, however, ignores the supply of research, an important determinant of the real quantity of research.

We present a four-equation model of resource allocation for state-produced research at agricultural experiment stations, consisting of demand and supply equations for research, an equation for allocating governmental revenues to station research, and an expenditure identity or equilibrium equation. The reduced-form expenditure equation derived from this model includes a traditional set of economic variables determining the demand for research and the supply of research and a few interest-group variables. Our model is tested with cross-sectional data on the forty-eight states of the United States, pooled together for the years of 1960, 1965, and 1970, for total expenditures by state agricultural experiment stations.

The outline of the paper is as follows: the first section specifies a theoretical model of resource allocation to state experiment station research; second section, the data base, the empirical specification of the model, and the regression results are presented and discussed; the last section presents the summary and conclusions.

A Model of Resource Allocation to State Experiment Stations

We propose a model of resource allocation for state-produced research at agricultural experiment stations consisting of demand and supply equations for applied research, an equation for allocating state revenues to station research, and an expenditure identity. We assume that demanders and suppliers of research in a state interact through the state legislature to determine the "equilibrium" size of expenditures on experiment station research.

The research of experiment stations is heavily production-oriented. Cline's data show that about 74% of agricultural experiment station research is production-oriented.[1] Much of agricultural research produces increments to basic knowledge or intermediate products (e.g., discoveries of new biological, chemical, physical, economic, or sociological relationships and advances in the methodology of experimental design and hypothesis testing) that enlarge the set of possibilities available to applied researchers (Binswanger and Ruttan, p. 23) but that may not directly increase production efficiency. However, without advances in basic knowledge, the applied research potential would be rapidly exhausted.

Applied research produces final research products. Some research maintains previous biological advances against adverse environmental conditions that might depreciate gains in crop yields and animal productivity (Griliches 1958; Evenson 1978), and other research (e.g., new or improved inputs, decision-making aids and schemes, and final agricultural products) attempts to increase output.

Demand

Applied agricultural research is an input in the production of agricultural output (Griliches 1964; Evenson 1968, 1971; Peterson and Hayami). We hypothesize a state aggregate demand function for indigenous applied agricultural research. At the state level, farmers, as producers, and land owners seem likely to be the primary beneficiaries. The price elasticity of demand for a state's agricultural products is much larger generally than for a nation's output. If a state produces a small fraction of total national or world output, indigenous agricultural research lowers its farmers' cost curves, increases its share of national output, and only slightly lowers the national (or world) price.[2] Thus, profit-maximizing

[1] The other 26% is allocated to a wide variety of research projects, e.g., home economics, consumer problems, rural and community development, environmental quality. We do not deny that these are important research areas, but we do choose to explain total research expenditures by concentrating on agriculture.

[2] Consider two geographic regions supplying $Q_i^s = S_i(P,\delta_i)$, $i = 1, 2$, where P and δ_i are the price received by suppliers of Q and a supply function shift parameter, respectively. The market demand function for Q is $Q^d = D(P)$, and market equilibrium requires $Q^s = Q^d$. However, the demand function facing region 1 is $Q^d{}_1 = D(P) - S_2(P,\delta_2)$, and the price elasticity of demand for region 1 is

$$\eta_{Q_1P} = (Q/Q_1)\,\eta_{QP} - (Q_2/Q_1)\,\epsilon_{Q_2P},\ \eta_{QP} \leq 0,\ \epsilon_{Q_iP} \geq 0,$$

where η_{QP} is the market price elasticity of demand for Q, ϵ_{Q_iP} is the price elasticity of supply of region i.

Also, the effect of a shift of the supply curve of region 1 due to advances in technology in that region on the market price of Q can be summarized as

farmers of a state should demand indigenous applied research that enhances their efficiency of production and improves their comparative advantage relative to farmers in other states or regions. The benefits from this research accrue largely as producers' surplus to indigenous farmers and as rents to the owners of inputs that are very inelastic in supply (Ayer and Schuh; Evenson 1979), e.g., land and water, other things equal. Farm input supply firms, processors of farm products, and local consumers also may benefit from agricultural research.

Although research products are a public good, indigenous demanders cannot expect to borrow all their research products from other states. Research output, a form of information, has the characteristic of a public good; use by one economic agent does not reduce the quantity available to others. The benefits to users vary, however, and some individuals may be made worse off as more individuals use research output. Potential users cannot be excluded easily; and, for social efficiency, such information should be made available to all potential users at the marginal cost of distribution (Arrow). Basic or intermediate agricultural research produced by one experiment station has the potential for being used (borrowed) by many states, but the potential for widespread direct interstate borrowing of final (applied) agricultural research products is usually more limited because their performance is frequently sensitive to local environmental factors and resource endowments. For example, studies by Griliches (1957) of hybrid corn and by Evenson (1978) of agricultural productivity show the incomplete nature of research-spillover across state and regional boundaries. Thus, a good substitute does not exist in agricultural production for indigenously produced applied research products that are location-specific or that are adapted more perfectly to the needs of indigenous clients than to others. Under these conditions, a state demand function for indigenously produced applied research exists.

The quantity demanded of indigenously applied agricultural research is hypothesized to be a function of the size and other characteristics of a state's agricultural output, agricultural input prices, farmers' education, extension, agricultural research in other states, and the price of indigenous applied research. The characteristics of a state's agricultural output are primary determinants of shifts in the demand for indigenous applied agricultural research. This emphasis on output follows from the positive contribution of agricultural research as an input in aggregate production function studies (Griliches 1964; Evenson 1968, 1971, 1978; Cline) and implicitly to farm profits. Also, the expected increase in farm profits from research oriented to insuring previous productivity gains against adverse and unpredictable environmental conditions is positively related to the size of output. The total value of preventing a 5% loss in output increases with the size of output. Furthermore, Evenson (1968) estimates that 30%–50% of agricultural research expenditures on crop and livestock and poultry research in 1967 were directed to maintenance research.

The diversity of indigenous agricultural products and the size distribution of farms may affect the demand for research. For a state, the intracommodity (within commodity) applicability of research (or economies of information usage) will usually be much higher than intercommodity (between commodity) applicability. Final research products (e.g., inbred corn lines, feedlot management systems, tillage machines, and fertilizer recommendations) are usually commodity specific. The expected returns from agricultural research are such that the marginal effect of a dollar of product output on the demand for research output diminishes as output increases. Thus, the number of agricultural commodities produced indigenously is expected to increase the aggregate demand for indigenous applied research.

The profitability of adopting new technology is a function of the reduction in cost per unit of output and the size of output. Because large farms have more units of output over which to apply cost savings than small farms, the operators of large farms have a greater demand for indigenous applied research because of potential profitability. Thus, holding the size and diversity of agricultural output constant, a larger share of large farms is expected to shift rightward the demand for indigenous applied research. (Feasible new technology might also have a large-farm bias.)

The tenure status of farmers also may affect

$$\frac{\delta_1}{P}\,\frac{\partial P}{\partial \delta_1} = \frac{(Q_1/Q)\epsilon_{Q_1\delta_1}}{\eta_{QP} - (Q_1/Q)\,\epsilon_{Q_1P} - (Q_2/Q)\,\epsilon_{Q_2P}},$$

where $\epsilon_{Q_1\delta_1}$ is the elasticity of supply of Q_1 with respect to δ_1.

At the national or international level, consumers are the primary beneficiaries of agricultural research. The price elasticity of demand for agricultural products at this level is low so the long-term impact of agricultural research is to lower the price of agricultural products and to benefit consumers.

the demand for research. Because benefits of indigenous research accrue as producers' surplus to farm operators and as rents to agricultural inputs that are most inelastic in supply (e.g., land), owner-operators of farms have a greater financial incentive to reveal their demand for indigenous research than do renters and seem likely to be more effective than the combination of absentee landowners and renter-operators (Evenson 1979). Thus, increasing the proportion of owner-operators is expected to increase (shift) the demand for applied indigenous research.

A shift in the relative prices of agricultural inputs can be expected to affect the demand for research. An increase in input prices reduces farmers' profits (and perhaps landowner rents) and can be expected to induce them to search for technical alternatives. These alternatives can be expected to save on the input(s) whose price(s) has increased and to increase the use of inputs that have become relatively cheaper (Hayami and Ruttan, Binswanger and Ruttan). This increase in input price shifts rightward the demand for indigenous applied research.

Farmers' education, extension, and research centers enhance the dissemination of information on agricultural technology. Education enhances the allocative ability of farmers (Huffman; Welch 1970). Extension decodes and repackages research findings so that the technical information can be better understood by farmers and can be applied at the farm level. Outlying research centers of the experiment station also aid the information-disseminating activity. Thus, higher schooling levels of farmers, larger extension activities, and a greater number of research centers speed the adoption of superior final research products, increase farmers' profits and landowners' rents, and increase the (share of) benefits from indigenous research to indigenous producers and owners of indigenous resources. Thus, an increase of farmers' education, agricultural extension, and research centers is expected to shift rightward the demand for research.

For a given state, Evenson (1979) has hypothesized that research output of other states may have two opposite effects on indigenous research demand. Most new research final products are not directly applicable to environmental and resource conditions in other states, e.g., a superior corn variety. Competing farmers in other states are placed at a competitive disadvantage unless new research products are developed for them. Thus, nonborrowable research output in competing states can be expected to shift rightward the demand for indigenous applied research. On the other hand, directly borrowable final research products (e.g., controls for livestock diseases, livestock feed additives, and farm management schemes) from other states obtained from input supply firms, veterinarians, extension personnel, and farm magazines will substitute for indigenous applied research and will reduce the indigenous demand for research.

We hypothesize that the quantity demanded of indigenous applied research is responsive to its price, the shadow price, given that it is not traded in the market at a price. The reason is that demanders face an opportunity cost for public-sector resources allocated to indigenous applied agricultural research. They must forego other public-sector goods and services (e.g., extension, education, welfare, roads) to obtain more indigenous research, or they must incur larger state tax payments, which means foregoing the private goods they otherwise could obtain. Thus, we hypothesize that the quantity demanded of indigenous applied research is negatively related to its shadow price.

Supply

In our model, indigenous applied agricultural research is produced and supplied by agricultural experiment stations. The final and intermediate products of experiment station research consist of technical publications (books, journals, and station bulletins), nontechnical publications, blueprints, new crop varieties or lines, new feed rations and additives, new environmental controls, new decision-making schemes, and training of researchers. The production of research requires, as inputs, the services of administrators, researchers (or scientists), research assistants, and secretaries, as well as scientific publications, office space and equipment, laboratory space and equipment, electronic computers, greenhouse space, experimental plots and farms, and research animals and plants. Salaries and personnel benefits, however, account for about 70% of total obligations (USDA 1966 and 1970).

As a first approximation, we assume agricultural experiment stations produce research outputs at minimum cost. These stations are

nonprofit institutions operating within public land-grant universities that have similar missions and goals, but that place different relative weights on the products from teaching, research, and service. Directors of experiment stations are the managers of these research-producing institutions. They differ in the amount and composition of their entrepreneurial activity, and we assume that they behave as if they are attempting to minimize the cost of producing research final products. This objective implies that directors do not change cost-minimizing input combinations because particular inputs (e.g., new buildings, prestigious research staff) yield satisfaction directly to them.[3]

The supply or cost function of indigenous applied agricultural research is hypothesized to be a function of prices of variable inputs (e.g., wage rates of research assistants and secretaries, rental rates on computers), of the quantity of research output, and of factors exogenous to current resource allocation decisions. The latter set of variables affects the efficiency of research production and, hence, the cost of research. They are the entrepreneurial activity of the station director, the characteristics of the station's researchers, the type of research appointments, and the existence of Ph.D. programs, extension contact with researchers, availability of borrowable research, number of final research areas, and the number of research centers.

Basic and applied research are creative activities; ideas must be combined so that something "new" is produced. This activity seems to require a sustained effort, with periods of intense mental preparation followed by reflection and, hopefully, enlightenment and then by writing and rethinking (Ladd). This implies that a significant share of a researcher's time and mental effort must be allocated to research. Thus, the productivity of research time seems likely to be low if individuals are continually being disrupted (by nonresearch activities) or if their working hours are primarily allocated to nonresearch activities (e.g., teaching, administrative-type activities), because this leaves less time for research. However, researchers may not have enough good ideas (and other resources) to keep their productivity high when all of their time is allocated to research. Thus, the effect of available time for research on the supply of research is a priori uncertain.

Researchers need sources of new ideas and knowledge to enhance the efficiency of producing research. Communication with extension personnel and colleagues is one source. When extension personnel interact with farmers, they learn of new problems facing farmers. Some problems may be solved by drawing upon existing knowledge, but others need to be redefined and relayed to researchers for further analysis. Thus, researchers interacting with extension personnel serve as a potential source of information transmittal on researchable problems.

Although the potential size of the stock of available knowledge is positively related to the number and quality of researchers at an institution, information exchange must occur before efficiency gains can be realized. Interdisciplinary research efforts facilitate communications across disciplines, but the organizational feature that seems most likely to foster exchange of information within and between departments of a university is a strong graduate Ph.D. program (Evenson 1971). Graduate courses taken by research assistants in the basic disciplines (e.g., statistics, chemistry, genetics, botany, economics) are an important source of knowledge and research techniques to be applied to station research projects. Graduate students in general may challenge the ideas of teachers and researchers and provide new ideas. Thus, strong graduate programs both within and outside of agriculture and forestry are expected to increase the efficiency of station research and to shift rightward the supply curve of research.

Borrowable research from other states is another source of new ideas and knowledge. Since the production of original research is expensive relative to distribution of results, borrowing research from other states reduces the costs of indigenous applied research. Not all available research, however, is useful. Basic research and intermediate research products generally have broad applicability because of their fundamental nature. Final or applied research products tend to be commodity- and geoclimatic-region-specific, so they may not be directly applicable in other states. To the extent that borrowing of final research products occurs, it seems likely to be confined

[3] Ruttan (1978) argues that in the United States the combination of centralized (USDA) and decentralized (state) systems of agricultural research results in an organizational structure that behaves similar to firms in a competitive market. Other researchers (e.g., Ault, Rutman, Stevenson) have assumed cost minimization for models of resource allocation in universities.

largely to states located in similar commodity geoclimatic regions (Evenson 1978). Thus, a larger quantity of available outside basic research is expected to shift rightward the supply of indigenous applied research.

The number of different research final-product areas, given the size of a station and the mix of research between crops and livestock, may affect the efficiency of research production. For a small station, supplying research products for a large number of commodities may mean spreading resources thinly, allocating most resources to final products and few to intermediate research products. Low production efficiency may occur because the station cannot take advantage of economies of size in producing research. Thus, increasing the diversity of a state's agriculture, and hence of applied agricultural research, is hypothesized to shift leftward the supply of research, other things equal.

Research centers (experiment stations and substations) are important laboratories for crop, livestock, and agricultural engineering research. The size and location of these centers are important organizational features of research (Evenson 1971, Binswanger and Ruttan). When environmental factors and commodities differ widely among regions within a state, decentralized research centers facilitate adapting technology to local conditions and displaying the results at field days. Centralization of research, however, permits taking advantage of economies of size in the use of expensive laboratory equipment, libraries, and administrative services. Centralization is also necessary for work requiring collaboration across disciplines by highly skilled researchers. Thus, the net effect of research centers on the supply of applied agricultural research is a priori unknown.

Revenue Allocation

In our model, demanders of station research do not pay suppliers of station research directly, but rather decisions are made at the state government level on the share of state revenue to be spent on indigenous applied agricultural research. We add a behavioral equation for allocating state government revenue (McMahon) to agricultural research.

We take the size of total state governmental revenues (includes intergovernmental transfers) as predetermined, but the share of these revenues allocated to agricultural research is endogenous. We hypothesize that political-economic clout is required to obtain funds for agricultural research (i.e., to affect the expenditure share) rather than letting available funds be allocated to the production of other state-provided goods, e.g., education, welfare, roads, parks. The director of the agricultural experiment station and interest groups, representing the interests of demanders of research, play key roles in obtaining these funds. The director initiates requests for research funds from the state legislature based upon his first-hand information of the research cost and (presumably) of the demand for research.[4] This latter information comes from his contact with producer groups, advisory boards, and input supply firms, from direct requests research, and from client feedback through extension personnel. Also, the size (or share) of state revenues allocated to agricultural research is affected by the director's activities (direct or indirect) to obtain legislative support for funding.

Demanders may lobby the state legislator directly or through interest groups to achieve their political influence. Interest groups exchange their votes in state governmental elections for favorable votes by legislators on legislation they support. Although consumer groups and environmentalists might lobby for certain kinds of agricultural experiment station research, we hypothesize that farm owner-operators, operators of large farms, and farm organizations are the strongest lobbyists for agricultural research. Because research benefits accrue largely as producers' surplus to farm operators and as rents to landowners, owner-operators of farms are expected to be stronger lobbyists than renter-operators. Also, because profitability of adopting new technology is a function of the change in cost per unit of output and the size of output, operators of large farms, having more units of output, are expected to be stronger lobbyists for agricultural research than operators of smaller farms.

General and commodity-specific farm organizations can be expected to use their political influence to get funds appropriated for research. The members of commodity-specific farm organizations seem likely to be more

[4] The budgeting process through which the director of the experiment station registers funding requests with the state legislature—directly, or indirectly through a university president and perhaps some governing board—may be an important factor for obtaining support for agricultural research.

homogenous in their research interests than general farm organizations, permitting them to be more decisive and influential in getting funds appropriated for research. The influence of these organizations, however, may be difficult to assess because of overlapping membership, uneven geographical coverage, and withholding of membership data.

The final equation of the model is an expenditure identity or equilibrium equation. A summary of the basic four-equation model we have developed of resource allocation to indigenous applied agricultural research is presented in table 1. The four endogenous variables are entrepreneurial activity of the station director, price and quantity of indigenous applied research, and expenditures on indigenous applied research. To obtain a reduced-form expenditure equation, we assumed that each of the four equations has a $\log_e$ linear form (see appendix). Because of the complexity of the expressions in terms of structural parameters, the coefficients of the reduced-form expenditure equation are difficult to sign.

The Empirical Analysis

The data base, the empirical specification of the variables, and the regression results from fitting the reduced form of the state expenditure equation for experiment station research are presented and discussed in this section.

The Data Base and the Variables

The basic data source on expenditures and other characteristics of the agricultural exper-

[a] A "χ" indicates that a variable appears in the designated equation.

iment stations is the USDA publication, *Funds for Research at State Agricultural Experiment Stations and Other State Institutions.* States in the conterminous United States are the unit of observation, and expenditures for the fiscal years of 1960, 1965, and 1970 are used as the dependent variable. Cross-sections are combined to provide a more rigorous test of the model and are chosen at the above five-year intervals to take advantage of the characteristics of agriculture reported in the *Census of Agriculture.*

Most of the variables are constructed on a state per capita basis by dividing them by the size of the state's population (U.S. Dep. of Commerce 1961, 1966, and 1971). We are treating public-sector agricultural research as a public good, but per capita expenditures have a more homoskedastic error term than total expenditures. Guttman uses per capita units in his empirical analysis. Finally, dividing both sides of the equation by the size of the population does not prevent one from using the fitted model to explain total expenditures on agricultural experiment station research.

The dependent variable is a state's grand total obligation of funds for the fiscal year by the experiment station (and other state institutions) less nonfederal funds available from fees, sales, and miscellaneous sources then divided by the size of its population. The fees and sales category is excluded because it is dominated by sales of livestock and crop products from research projects.[5] Agricultural output is measured as net annual sales per capita (total value of farm products sold less purchases of livestock and poultry and of noncommercial feeds for livestock and poultry), (U.S. Dep. of Commerce 1963, 1967, and 1973) lagged one year. An index of concentration (diversity) of a state's agricultural output is constructed as the summation of the squared production share of each of eighteen different agricultural commodities or commodity groups. The index is largest if a state's agricultural output consists of only one commodity or commodity group (it is one), and is smallest if a state produces an equal value of each of eighteen different commodity groups (18/324). For input prices, we use only a state's annual average hourly wage rate for hired labor, without board and room (USDA 1961, 1965, and 1970) lagged one year. The main source of interstate variation in other farm input prices is transport costs, except for land. Land rental data for comparable agricultural land do not exist, and land price differences reflect quality differences and a number of economic forces not related to its current rental value for agricultural production. The education level of farm operators is a Welch-weighted (Welch 1966, 1970) average number of years of schooling completed by farm operators (U.S. Dep. of Commerce 1962, 1968, and 1972). Extension is the grand total of a state's expenditures on extension per capita, lagged one year (USDA).

We constructed two measures of research activity outside a given state from data made available to us by Robert Evenson (and described in Evenson 1978). The relevant set of states to consider in constructing these variables was determined by the boundaries of geoclimatic regions and subregions derived from the 1957 *Yearbook of Agriculture* (see figure 1). These areas have relatively homogeneity of soils and climatic factors. The subregional applied-research stock (competitive research) is the summation of past commodity-specific livestock and crop research expenditures, and applied agricultural engineering and farm management research expenditures aggregated over states with similar agricultural subregions outside the state. Applied research expenditures were assumed to have a thirty-year useful life, and linear weights were applied to aggregate over time with seven years of increasing, eight years of constant, and fifteen years of declining weights.[6] Basic research (noncommodity specific research) is applicable over a wider geoclimatic area. The regional basic research stock (borrowable research) is the summation of past basic research expenditures for states in similar geoclimatic regions outside the state. Basic research was assumed to have a forty-year useful life, and linear weights were applied to aggregate over time with seven years of increasing, eight years of constant, and twenty-five years of declining weights. Outside applied and basic research are in per capita units.

[5] The presence of measurement errors in the dependent variable, say due to its inclusive nature, will not generally affect the statistical properties of the estimated coefficients of the model. These errors, however, would affect the qualify of forecasts from the model.

[6] The time shape for the weights is based upon the results of a partial correlation scanning analysis across varying time shapes by Evenson (1978). The pattern chosen gave high correlation of the research variable with agricultural productivity. The same time shape is imposed on all states.

Figure 1. U.S. agricultural geo-climate regions and subregions.

Four characteristics associated with agricultural experiment stations follow. A research center's variable is derived as the number of research stations and substations (USDA, *Professional Workers in State Agricultural Experiment Stations*), including main campus, per 10,000 farms. The average share of budgeted time for research is derived as the number of full-time equivalent station researchers divided by the total number of station researchers engaged full- or part-time in research (USDA, *Funds for Research*). Two variables measuring the size of the Ph.D. degree programs are derived. The station Ph.D.-to-research faculty ratio is the (three-year centered) average number of Ph.D. degrees earned in agriculture and forestry from departments associated with the agricultural experiment station (U.S. Dep. HEW, *Earned Degrees Conferred*) divided by the number of full-time equivalent station researchers. The Ph.D. degrees in other areas is the annual average (two years) number of Ph.D. degrees earned in other areas (excluding agriculture and forestry) at universities associated with agricultural experiment stations (U.S. Dep. HEW, *Earned Degrees Conferred*) relative to the size of the state's population.

The state budget constraint is total revenue per capita of the state government from all sources, including intergovernmental transfers (U.S. Dep. Comm., *Statistical Abstracts*).[7] Income generated in the state, types of taxes, and willingness of the state's people to be taxed are important determinants of the size of this budget constraint. Farm size distribution is measured as the share of large farms (sales ≥ $40,000) and the share of medium-sized farms (sales $2,500–$39,999). The proportion of owner-operators is a weighted-average number of full owners and of part owners. Full

[7] For federal matching funds, each state much at least match the federal fund; with nonfederal funds, including state appropriations, to qualify for the federal support of research. In all states, nonfederal funds for experiment station research are considerably larger than the minimum required to be eligible for federal grant funds. Thus, at the margin, additional federal matching funds have an income but not a price effect.

owners are given an arbitrary weight of 1 and part owners a weight of 0.5. The only accessible farm organization membership data are for cooperatives. The cooperative membership variable is the total estimated number of memberships in marketing, farm supply, and related service cooperatives (USDA, *Statistics of Farmer Cooperatives*) per capita. Because a farmer can be a member of more than one cooperative, there is considerable double counting, but this will be a desirable characteristic when a cooperative's influence is derived from "speaking for its members."

Table 2 presents a summary of the empirical variables, including the symbols associated with each variable, and the sample means and standard deviations of the variables. The table shows that the mean value of expenditures on state experiment station research over the 144 observations is \$1.40 per person and the standard deviation is \$0.93 per person. (No variable measuring the prices of indigenous research inputs is included in the empirical model. There are two main reasons for this inclusion. First, wage and salary data for researchers and research assistants by university are difficult to obtain. Second, observed cross-sectional variation in these prices may be meaningless. Part of the variation would be due to quality differences in the services these individuals perform, to previous experience, and to nonwage characteristics of their job, e.g., learning opportunities, pleasantness of surroundings, city size.)

The Results

The results from fitting a reduced-form expenditure equation by the method of least squares to the 144 pooled observations are reported in table 3. The equation is fitted with interaction terms between ln (*AGOUT*) and *CONC* and between *LARGE* and ln (*ARES*) and with two time-period dummy variables. The impressive characteristic of the results is the generally good performance of the explanatory variables and of the regression model as a whole. The results imply that the demand for agricultural research is price inelastic and that the supply

Table 2. Summary Statistics for Expenditures on U.S. State Agricultural Experiment Station Research, 1960–1965–1970

Variables	Symbol	Unit	Mean	St. dev.
Expenditures on experiment station research per capita	*R*	\$0.1 per person	14.0	9.3
Net agricultural output per capita	*AGOUT*	\$s of output per 1,000 people	2,359.0	2,174.3
Index of commodity concentration of agricultural output	*CONC*		0.21	0.08
Proportion large farms	*LAR*		0.07	0.06
Proportion medium-sized farms	*MED*		0.53	0.15
Proportion owner-operator	*OWN*		0.73	0.09
Wage rate of hired farm labor	*WAGE*	\$ per hour	1.20	0.31
Index of farmers' education	*ED*		1.49	0.28
Extension expenditures per capita	*EXT*	\$ per person	1.39	0.81
Research centers per farm	*CEN*	Centers per 10,000 farms	3.06	4.06
Subregional applied research stock per capita	*ARES*		16.12	19.80
Regional basic research stock per capita	*BRES*		3.92	5.47
Budgeted share of research time	*SR*		0.70	0.12
Ph.D. degrees earned in agriculture and forestry per full-time equivalent researcher	*APHD*	Ph.D. degrees per researcher	0.07	0.08
Ph.D. degrees earned outside agriculture and forestry per capita	*OPHD*	Ph.D. degrees per 1,000 people	0.03	0.03
State revenue per capita	*REV*	\$1,000 per capita	0.984	1.02
Coop membership per capita	*COOP*	Member/1,000 people	2.29	1.85

Constant		−1.283	−1.96
R^2			0.92

[a] D_{70} and D_{60} are dummy variables for the years of 1970 and 1960, respectively. The constant includes effects of the year 1965 and the proportion of small farms.

elasticity is positive. The conclusion concerning the price inelasticity of demand for agricultural research was derived by comparing the signs of the estimated reduced-form coefficients with predicted signs of reduced-form coefficients based upon hypothesized values of structural coefficients and of the price elasticity of demand for research.

The positively and statistically significant coefficient of agricultural output is consistent with our hypothesis that the demand for agricultural experiment station research is positively related to the size of agricultural output. The negative coefficient on the *AGOUT-CONC* interaction variable implies that the elasticity of research expenditures with respect to output is reduced (increased) as a state's agricultural commodities become more concentrated (diverse). This result supports the hypothesis of commodity specificity of research final products. The elasticity of research expenditures with respect to agricultural output, evaluated at the sample mean of *CONC*, is 0.18. Although this estimate may seem small, the estimated coefficient of ln (*AGOUT*), is an estimate of the net effect of several different structural parameters (see appendix). The results imply that larger agricultural output shifts rightward the demand for research, but the exact magnitude of the shift cannot be determined. The elasticity of research expenditures with respect to *CONC*, evaluated at the mean of ln *AGOUT*, is negative. We hypothesized that greater diversity (concentration) of agricultural output would shift the demand for research to the right (left) and the supply schedule upward (downward). The negative elasticity is consistent with this hypothesis.

The size distribution of farms and the tenure status of farmers affects research expenditures through the demand and allocation equations. Expenditures are positively related to the proportion of large farms and to the proportion of medium-sized farms. (We find that variables measuring the size of farm output per capita

and the proportion of farms by size class are a superior specification to the number of farms per capita in each size class.) These directional effects are consistent with the positive hypothesized effects of these variables on the demand for research and on state revenue allocation. The marginal effect of *LARGE* on research expenditures depends on the size of the subregional applied research stock. The estimated coefficient of the interaction term between *LARGE* and ln *ARES* is negative. (When the interaction term between *LARGE* and ln *ARES* is excluded from the regression, the estimated coefficient of *LARGE* is positive but has a *t*-ratio of only 1.0. The estimated coefficient of an interaction between *MED* and ln *ARES* was not significantly different from zero at the 5% level.) It suggests that operators of large farms have greater ability to borrow (or have a greater incentive to search and experiment with) applied research from the available stock in similar subregions outside their state than have other farmers. This opportunity to borrow reduces their demand and willingness to lobby for indigenous applied agricultural research. At the sample mean value of ln *ARES*, the estimated percentage change in research expenditures due to a one percentage point change in the share of large farms is 0.80. Since the estimated coefficient of *MED* is 0.46 (not significantly different from zero at the 5% level), a one percentage point increase in the share of large farms (*LAR*) has a much larger effect on research expenditures than does a one percentage point increase in the share of medium-sized farms. This finding is consistent with differences in expected returns from indigenous agricultural research by these sizes of farms. The estimated coefficient of the proportion of farm owner-operators has the expected positive sign.

The positive and statistically significant estimated coefficient of the hired farm wage rate is consistent with the hypothesis of input prices shifting rightward the demand for indigenous applied agricultural research. The result suggests that farmers in states with high farm wage rates have demanded research to reduce the rising relative labor costs of agricultural production.

The information-related variables, except for farmers' education, have positive estimated coefficients. We hypothesized that both the demand for and the supply of research would be shifted to the right by extension activities. The positive coefficient is consistent with this hypothesis. The number of research centers per farm has a significant positive effect on research expenditures. Although this variable was expected to shift the research demand schedule to the right, the supply of research might shift in either direction, so the positive coefficient is consistent with our hypothesis. The negative and statistically significant coefficient of farmers' education is puzzling. We hypothesized that increasing farmers' education shifts rightward the demand for indigenous research and increases desired research expenditures. The estimated coefficient does not support this hypothesis. The result has the surprising implication that farmers' education substitutes for public sector indigenous research. This might arise from more educated farmers depending more heavily on private sector research (and less on public sector validation) or on borrowing large amounts of applied research from other states. The estimated coefficient of an education-applied research interaction term, however, was not significantly different from zero.

The performance of the variables measuring the potential research stock outside a state shows that external factors affect a state's research expenditures. The positive and statistically significant coefficient of subregional applied research suggests rivalry; applied research in similar subregions outside a state is competitive. A state's farmers demand indigenous research in an attempt to minimize their loss of comparative advantage to other farmers in similar subregions. The negative coefficient of regional basic research suggests that states with a greater potential for borrowing research reduce their expenditures on research. This can arise from a rightward shift in the supply of research, provided the demand for indigenous research products is price inelastic.

The budgeted share of research time and the two Ph.D. variables are supply-side control variables. Expenditures on research are positively related to the share of research time of station research staff. Raising the share of a researcher's time allocated to research may either raise or lower efficiency (the supply curve of research). If the demand for research is price inelastic, then the positive coefficient implies a loss in efficiency.

Expenditures on research are negatively (but not significantly) related to the station Ph.D.-to-researcher ratio. Research expendi-

tures are positively related to the number of Ph.D. degrees earned in areas other than agriculture and forestry within universities associated with agricultural experiment stations. The size of these Ph.D. programs provides an index of the quality of the graduate program in nonagricultural areas and the potential for intra-university borrowing of knowledge by station faculty and graduate students. When the demand for research is price inelastic, this positive coefficient contradicts the hypothesis of an efficiency gain, but it might reflect the general willingness of the public to support all kinds of research at land-grant universities.

The estimated coefficient of state revenue is positive, and the revenue elasticity of expenditures is 0.18. Thus, other things equal, states with greater financial ability do spend more on experiment station research. This finding supports Schultz's observation (1971) that wealthier states spend more on agricultural experiment station research than do less wealthy states and Peterson's finding (1969) that expenditures on experiment station research are positively related to a state's level of nonfarm income.

The estimated coefficient of cooperative membership is positive and significantly different from zero. Membership in this type of farm organization seems to influence state appropriations for agricultural research. Multiple membership in cooperatives also seems to be a significant factor in explaining research expenditures, because alternative empirical definitions of the coop variable that removed some or most of the overlapping membership (e.g., volume of business) performed less well.

Implications and Conclusions

Our results show that agricultural experiment station research expenditures have been responsive to economic and institutional forces. Experiment station research has been substituted for farm labor in an era of rising wage rates. Undoubtedly, much of this research has been induced to develop labor-saving (augmenting) techniques. Likewise, the finding of positive effects of the proportions of large and medium-sized farms and of owner-operated farms on research expenditures suggests that these groups affect the nature of research undertaken. However, the support for station research by the operators of large farms declines if there is a large quantity of applied research available from similar subregions in other states.

The wealthier (based upon per-capita state government revenues) and more agriculturally oriented states (as measured by size of agricultural output per capita) have supported and will likely continue to support public agricultural research in the future (Schultz 1971). In an era of relatively declining federal support, the implications for agricultural research stations in less affluent and less agriculturally oriented states are rather pessimistic. Farmers in these states may encounter increasing comparative disadvantage relative to farmers in states with similar geoclimatic regions, if their competitiveness is not maintained by a flow of applied research products. Also, if these states are characterized by smaller-sized farming operations, the capacity of these farmers for borrowing final research products from other states is further reduced. Finally, if other states in similar geoclimatic regions are suffering similar economic fates, the potential for borrowing basic research will be reduced.

The supply side of our model includes some implications for the organization of the experiment station. Expenditures for research are positively related to the budgeted share of staff research time and to the number of research centers per farm and negatively related to agricultural Ph.D.s earned per full-time equivalent station researcher. Assuming the demand for agricultural research is price inelastic, these results suggest that decreasing nonresearch commitments of researchers and increasing the regional specificity of research within the state through more research centers will decrease productivity of the station. Increasing the ratio of graduate students to station researchers may actually increase productivity.

In periods of fiscal restraint and declining real resources due to inflation, directors may find it necessary to reduce expenditures and reallocate station resources. To the extent that they are not bound by institutional constraints, substituting less costly research assistants for scientists, reducing the share of research time per scientist, and consolidating the number of outlying research centers may both reduce resource needs and increase station productivity.

Past research has shown that improved information has a positive impact on the demand for new agricultural inputs. In this study we

find that extension expenditures have a positive effect on research expenditures, but that farmers' schooling has a negative effect. Extension aids in the dissemination of information and research final products and in the identification of farm problems needing research. This complementarity should not be overlooked by state legislatures, especially if the federal government implements reductions in both research and extension funding. Although the education result is troublesome, holding all other factors constant, it may indicate that better-educated farmers realize the pervasive nature of public research and attempt to capture the benefits through private agricultural research. Thus, they may engage in their own research or purchase privately supplied research inputs.

Cooperative membership has a positive effect on research expenditures. To the extent that coop membership is a proxy for membership in farmer-oriented public interest groups, these results suggest that, if a state's farmers are better organized (Guttman), they will have a stronger effect on state allocations to agricultural research. Our results also imply that the multiplicity of farmer membership in these public interest groups increases their effect on research expenditures.

Some of the key variables in our model are expressed in per capita units as opposed to total units. Because the impact of a state's population on experiment station size may be of interest, we used our results to derive the total expenditure elasticity with respect to a state's population, valued at the sample mean of concentration and proportion of large farms and holding per capita state revenue constant. The implied elasticity estimate is 0.85, implying that states with large populations have the larger stations, other things equal.

The impact of potential cutbacks in federal funding for state experiment stations is a concern of the agricultural research system. In our model, federal funds for experiment station research are included in the state revenue variable. For 1960, 1965, and 1970, federal funds for experiment station research averaged 0.09% of total state revenues, and the state revenue expenditure elasticity of research expenditures was 0.18. Thus, a 10% decrease in federal support for station research implies a 0.9% decrease in state revenue and a 0.15% fall in state expenditures on agricultural research. Our analysis implies that the adjustment for an experiment station in an average state would not be drastic, but the adjustment may be more severe for stations in states where federal funding of station research is a larger-than-average share of total state expenditures.

Appendix

The Mathematics of the Reduced-Form Equation

The model of resource allocation for agricultural research contains a demand equation, a supply equation, a revenue allocation equation, and an expenditure identity. In $\log_e$ linear form, the model is as follows:

$$\text{(1)} \quad \ln Q = \alpha_1 \ln X_1 + \alpha_2 \ln X_2 + \alpha_3 \ln X_3 + \delta \ln P,$$

$$\text{(2)} \quad \ln P = \beta_2 \ln X_2 + \beta_4 \ln X_4 + \beta_5 \ln X_5 + s \ln Q + \theta_1 \ln A,$$

$$\text{(3)} \quad \ln E = \gamma_3 \ln X_3 + \gamma_5 \ln X_5 + \gamma_6 \ln X_6 + \theta_2 \ln A,$$

$$\text{(4)} \quad \ln E = \ln Q + \ln P,$$

where δ, s, α_i, β_i, θ_i, and γ_i are unknown parameters; and where Q is quantity of indigenous applied research; P, price of indigenous applied research; E, revenue for (expenditure on) indigenous applied research; A, entrepreneurial activity of the station director; X_1, variable(s) entering demand equation only; X_2, other variable(s) entering demand and supply equations; X_3, other variable(s) entering demand and allocation equations; X_4 variable(s) entering supply equation only; X_5, other variable(s) entering supply and allocation equations; and X_6, variable(s) entering allocation equation only.

Equations (1)–(4) are solved to obtain the reduced-form expenditure equation:

(5)

$$\ln E = \{\theta_2/[\theta_2(1 - \delta s) - \theta_1 (1 + \delta)]\}\{\alpha_1(1 + s) \ln X_1 + [\alpha_2(1 + s) + \beta_2(1 + \delta)] \ln X_2 + [\alpha_3(1 + s) - \frac{\theta_1}{\theta_2}(1 + \delta)\gamma_3] \ln X_3 + \beta_4(1 + \delta) \ln X_4 + [\beta_5(1 + \delta) - \frac{\theta_1}{\theta_2}(1 + \delta)\gamma_5] \ln X_5 - \frac{\theta_1}{\theta_2}(1 + \delta)\gamma_6 \ln X_6\}.$$

There are thirteen structural parameters in the six reduced-form coefficients of equation (5), so identification of these structural parameters would require buying a relatively large set of nonzero restrictions on the included structural parameters. This exercise is left to the interested reader.

Participation in Farm Commodity Programs: A Stochastic Dominance Analysis

Randall A. Kramer and Rulon D. Pope

The net benefits of participation in farm commodity programs are analyzed with a normative risk model based on stochastic dominance theory. Utilizing entire probability distributions of participation and nonparticipation net returns, the impacts of alternative program features and farm size are investigated. Small changes in program parameters are found to affect participation decisions. It also is demonstrated that farm size can influence participation choices.

Key words: commodity programs, risk, stochastic dominance.

The decision to participate in farm commodity programs has traditionally been a voluntary one. Under current legislation a farmer may elect to participate by fulfilling any set-aside requirements that are in effect. For example, in 1979, set-aside was required for wheat, corn, sorghum, and barley. Previous research on commodity programs has focused primarily on either (*a*) the impacts of the programs on supply response (Houck and Ryan, Just) or (*b*) the impacts of the programs on asset values (Boehlje and Griffin, Harris). The intent of this paper is to contribute to the understanding of the economic incentives facing a grower choosing to participate or not to participate in commodity programs by assessing the benefits (improved income or income stability) and costs (set-aside acreage). Though expected returns have been used in analyzing program participation decisions (Robbins), the purpose of this paper is to present a procedure to analyze participation utilizing the entire probability distributions of net benefits. Since there is ample evidence that farmers respond to risk as altered by commodity programs (Just), the need for including risk in studying participation is apparent. A normative risk model, based on stochastic dominance theory, is used to investigate the impact of alternative program features and farm acreages on the participation decision of California field crop farmers. The stochastic dominance model also is compared to the more restrictive mean-variance analysis. Particularly where skewness is altered by the program, it is argued that expected utility, using empirical distributions, is likely to be more appropriate and more illuminating for investigating program choices.

Commodity Program Features

The commodity programs under the Food and Agriculture Act of 1977 feature a dual price system utilizing loan rates and target prices. Loan rates are used in determining the value of crops for nonrecourse loans through the Commodity Credit Corporation (CCC). A program participant can place any amount of production in approved storage and receive a loan equal to the loan rate multiplied by the quantity of grain in storage. If the average market price falls below the loan rate, the participant can forfeit the stored crop in lieu of repaying the loan. Consequently, the loan rate generally places a floor under the commodity price for a participant.

Target prices are used in the determination of deficiency payments to producers. Deficiency payments are activated when the average market price of a commodity over a specified period falls below the commodity's

---

The authors wish to thank B. Delworth Gardner and anonymous reviewers for helpful comments.

target price. The difference between the target price and the higher of the average market price or the loan rate establishes the per unit deficiency payment for participants. The national loan rate, which is used in the determination of maximum deficiency payments, may differ from the loan rate encountered by a farmer obtaining CCC loans, because the latter loan rate is adjusted for regional conditions.

Deficiency payments are multiplied by a program allocation factor which is not known in advance by farmers. It is legislated to be between 0.8 and 1.0. Deficiency payments are made on program yields rather than actual yields. The program yields are established by Agricultural, Stabilization, and Conservation Service (ASCS) county committees.

To be eligible for price and income supports, farmers must satisfy set-aside requirements (if any). In general, the set-aside acreage must be devoted to conservation practices. Additional voluntary diversions are encouraged through extra payments. Farmers meeting set-aside requirements also are eligible for disaster payments. Disaster payments are made for prevented plantings and unusually low yields. For further information on the commodity programs, see Johnson and Erickson.

A farmer considering the participation decision must weigh the program benefits resulting from the nonrecourse loans, deficiency payments, and disaster payments against the program costs resulting from the set-aside requirements. Given the operational complexity of the commodity programs, the participation decision requires careful analysis. The variability and other moments of economic returns are important considerations in farm level decision making (Lin, Just). Moments other than the mean are likely to be especially relevant in farm program participation decisions, because of the alleged risk-reducing nature of the programs.

Motivation for Stochastic Dominance Analysis

The methods for analyzing optimal choices or eliminating inefficient choices for a class of risk preferences are numerous in theory, but relatively few in practice. The method most used for continuous choice efficiency analysis is quadratic programming (or MOTAD). Often the efficient set is reduced to a single optimum plan based upon the mean-variance model of Freund. Stochastic dominance is a popular tool for discrete choice efficiency analysis. It makes pairwise comparisons of probability distributions, F_i and F_j, from a finite set of choices in order to determine if one is inefficient and should be discarded from the efficient set. When there is a continuous mixing of returns on various crops (whole farm planning), dominance procedures must compare an infinite number of farm plans. As a result, little progress has been made toward developing a portfolio algorithm based upon dominance considerations. Though mean-variance analysis easily can accommodate whole farm planning, its propriety rests upon the validity of return distributions or decision maker preferences which consider only mean and variance. Levy and Markowitz have argued that increasing the complexity of the approximation in mean and variance of a general utility function may improve mean-variance results. Yet, the fundamental issue is the existence and magnitude of higher order moments.

For these and other reasons, proponents of expected utility analysis have been critical of mean-variance approaches except under normality. Though the quadratic utility function gives an expected utility function in mean and variance without assuming normality, it exhibits increasing risk aversion, a property which seems to have little empirical or theoretical support (see Pratt for a discussion). It seems reasonable to suppose that returns both in and out of the farms program are not normally distributed (or symmetric) because the program serves to reduce the probability of low income events.

A remaining issue concerns the importance of modeling the optimal farm plan. Stochastic dominance performs well when there is a finite, and hopefully small, number of crop choices (such as those delineated by field boundaries in irrigated agriculture). On the basis of a 1979 survey of California farmers, it appears that there was little recent change in crop configuration in response to government programs; that is, the participation decision was conditional on crop selection.[1] Even in

[1] A mail survey was sent to 826 California farmers in nine counties. Information was requested on participation behavior in 1978 and 1979. Most respondents either participated in both years or did not participate in both years. A small number (25) participated in only one of the two years. More than half of this group (52%) altered their acreage of program crops by less than 15%. In all cases there were no systematic changes across farms with similar endowments.

the area of California considered, a farm may have few production or marketing alternatives in the short run, when specialized machinery investments, contracts, and field configurations for irrigated agriculture are considered. However, one suspects that continuation of the programs would lead to systematic adjustments. Therefore, the decision whether or not to participate in the farm programs, given crop acreages, seems to have both positive and normative economic relevance. This suggests that the generality implied by expected utility and stochastic dominance may be applied easily.

Stochastic Dominance

Stochastic dominance allows the ranking of probability distributions for different classes of risk attitudes. Although the concept of stochastic dominance is relatively new, a rather extensive literature on the subject has emerged (see Whitmore and Findlay for a bibliography). Recently Meyer has generalized the stochastic dominance theorems. As the earlier results are special cases, only Meyer's conceptual framework will be presented.

Meyer's work depends on the Arrow and Pratt measure of local risk aversion, $r(x) = -U''(x)/U'(x)$, where, generally, x is income or wealth. While the sign of the second derivative of the utility function, $U''(x)$, indicates whether a decision maker is risk-averse $[U''(x) < 0]$ or risk prone $[U''(x) > 0]$, its magnitude provides no insight into risk attitudes. This is because $U''(x)$ is affected by linear transformations, although the utility function is not. The Arrow-Pratt measure avoids this problem. It is also important to note that any utility function can be written in terms of $r(x)$(Pratt).

Meyer considers the set of decision makers, $U[r_1(x), r_2(x)]$, with utility functions that satisfy

$$r_1(x) \leq -U''(x)/U'(x) \leq r_2(x) \text{ for all } x.$$

In other words, the degree of risk aversion at all points x lies between $r_1(x)$ and $r_2(x)$ for all agents in the set The convenience of Meyer's approach is that different sets of decision makers can be considered by varying the lower bound, $r_1(x)$ and the upper bound, $r_2(x)$. Since $r(x)$ is generally estimated, it is convenient to consider not only point, but interval estimates of $r(x)$ as well. Thus, $r_1(x)$ and $r_2(x)$ may be the upper and lower bounds of the interval. Also, given such a set of decision makers [or a single decision maker for whom we are uncertain of $r(x)$], it can be determined whether or not all persons in the group prefer one cumulative distribution, $F(x)$, to another one, $G(x)$, or are indifferent. If $F(x)$ is preferred to $G(x)$, $F(x)$ is said to dominate $G(x)$.

If $F(x)$ is preferred to $G(x)$ for all permissible $r(x)$, then it must be true that

$$\int_0^1 U(x)f(x)dx - \int_0^1 U(x)g(x)dx = \int_0^1 U(x)[f(x) - g(x)]dx > 0,$$

where $f(x)$ and $g(x)$ are probability density functions defined over the range of the random variable specified here as [0, 1]. Integrating the above by parts yields

$$\int_0^1 [G(x) - F(x)]U'(x)dx = E_fU(x) - E_gU(x).$$

If the above expression is minimized over $r(x)$ and is positive, then all decision makers for whom $r_1(x) \leq r(x) \leq r_2(x)$ prefer $F(x)$ to $G(x)$ [even the decision maker least prone to choose $F(x)$]. Thus, the problem can be cast in a control framework with $U'(x)$ as a state variable and $r(x)$ as a control variable as follows:

$$\underset{r(x)}{\text{Max}} - \int_0^1 [G(x) - F(x)]U'(x)dx,$$

subject to the equation of motion,

$$[U'(x)]' = U'(x)[U''(x)/U'(x)],$$

and the constraints on the control,

$$[-U''(x)/U'(x)] - r_1(x) \geq 0$$
$$[U''(x)/U'(x)] + r_2(x) \geq 0,$$

and the initial condition, $U'(0) = 1.0$.[2]

This problem minimizes the difference in expected utility between $F(x)$ and $G(x)$ with respect to $r(x)$. The solution to this problem determines whether $F(x)$ is preferred or indifferent to $G(x)$ for all decision makers in the class, $U[r_1(x), r_2(x)]$, for any specified $r_1(x)$ and $r_2(x)$. Meyer shows that this control problem is a "bang-bang" one; that is, the solution value of the control variable will be either the upper or lower bound. Finally, if $F(x)$ is preferred to $G(x)$, then it has been shown that the objective functional must be nonnegative.

[2] Meyer assumes that $F(x)$ and $G(x)$ have points of increase on a bounded interval taken for simplicity to be [0, 1], thus, the limits of integration. The initial condition is a harmless normalization necessary to ensure that a unique maximum exists.

Two special cases of Meyer's formulation can be considered by varying the risk-aversion bounds. First, if $r_1(x) = -\infty$ and $r_2(x) = +\infty$, then the set of agents includes all decision makers. The first degree stochastic dominance theorem states that for any two probability distributions, $F(x)$ and $G(x)$, the expected utility of $f(x)$ exceeds the expected utility of $g(x)$, if and only if $F(x) \leq G(x)$ for all x with strict inequality for at least one x. In other words, all decision makers will prefer $f(x)$ to $g(x)$, if and only if the cumulative function $G(x)$ lies everywhere above $F(x)$.

The second special case is when $r_1(x) = 0$ and $r_2(x) = +\infty$. In this case the set includes all risk-averse agents. The second degree stochastic dominance theorem states that for all risk-averse agents, the expected utility of $f(x)$ exceeds the expected utility of $g(x)$, if and only if

$$\int_0^1 [F(y) - G(y)]dy \leq 0$$

for all x, and $G \neq F$ for at least one x. In other words, if two cumulative distributions cross, $f(x)$ is preferred to $g(x)$, if and only if the area beneath $F(x)$ and to the left of x is less than the area below $G(x)$ and to the left of x for any x. An application of first, second, and third degree stochastic dominance to technology choice has been presented by Anderson.

Though the above description has utilized continuous probability density functions, it clearly carries over to cases of discrete distributions by a simple modification of the above results by identifying integration as an appropriate summation. Using Meyer's formulation, dominance results are obtained for decision makers whose preferences lie in a specified interval.

Meyer's more general approach allows the ranking of distributions that could not be ranked by previous stochastic dominance theorems, such as first or second degree stochastic dominance. In one simple algorithm, first degree, second degree or more general dominance efficient sets can be delineated. Without reference to an individual decision maker, suppose it were determined that participation was preferred to nonparticipation for all $r(x)$ in (.0000001, $+\infty$). This implies that nearly all risk averters (those with $r(x) > .0000001$) would participate. Yet, second degree stochastic dominance could not have given us this information. Thus, even without knowing the quantitative measure of $r(x)$, we could be reasonably sure that a risk-averse decision maker would prefer participation. By varying $r_1(x)$ and $r_2(x)$, the effects of the magnitude of risk aversion on choices can be studied (see Pope for further discussion of the advantages of Meyer's approach). Finally, as stated earlier, a second reason for interest in the interval approach is that it allows more robust analysis than when point estimates of $U(x)$ and $r(x)$ are given. This is because these functions generally must be estimated, and, hence, interval estimates may be more appropriate than point estimates.

Model and Data

A nonparticipant's net revenue, summed over K crops, can be expressed as

(1)
$$NR_{np} = \sum_{i=1}^{K} \{[(P_i - HC_i) \cdot Y_i \cdot A_i] - PHC_i\},$$

where P_i is the market price; HC_i, average variable harvest cost per unit; Y_i, yield per acre; A_i, the total number of acres; and PHC_i, total variable preharvest cost, all for the ith crop. In this analysis fixed costs are ignored as they are assumed not to affect the participation decision of an individual farmer in the short run.[3] Harvest and preharvest costs are separated because harvest cost is assumed to be stochastic, varying with yield.

The net revenue for a program participant growing K crops can be expressed as

$$(2)\quad NR_p = \sum_{i=1}^{K} \{[(P'_i - HC_i) \cdot Y_i + DFP_i + DSP_i] \cdot (A_i - PHC_i) \cdot (1 - S_i)\},$$

where P'_i is higher of the local price or local loan rate for the ith crop;

DFP_i is per acre deficiency payment, or

$$\text{Max}\ [(TP_i - NP_i), 0] \cdot (PY_i - DY_i) \cdot AF_i;$$

DSP_i is per acre disaster payment, or $a_i \cdot TP_i \cdot DY_i$;

[3] Throughout, we model the preference function over the distribution of net returns. Only empirical analysis can determine whether omitting wealth or consumption is important, since utility theory does not determine whether wealth, consumption, income, rate of return, loss, etc., are utility function arguments. For constant risk aversion, changes in wealth or fixed costs will do nothing to the ranking of preference over distributions. For decreasing or increasing risk aversion, such changes will alter boundary intervals. However, because the total risk-aversion range of interest is analyzed, the qualitative results will not be affected.

AF_i is program allocation factor (assumed fixed);
TP_i is target price;
NP_i is higher of the national average market price or national loan rate;
PY_i is program yield;
DY_i is disaster yield, or

$$\text{Max } [(b_i \cdot PY_i - Y_i), 0];$$

a_i is 0.50 for wheat and feed grains and 0.33 for cotton;
b_i is 0.60 for wheat and feed grains and 0.75 for cotton; and
S_i is set-aside proportion, all for the ith crop.[4]

Deficiency payments are not made if $(TP_i - NP_i)$ is nonpositive. Also, no disaster payments are made if $(b_i \cdot PY_i - Y_i)$ is nonpositive. Equation (2) says that a farmer will receive an amount equal to the higher of the market price or loan rate, plus any deficiency and disaster payments, minus harvest and preharvest costs, all multiplied by the amount produced. As indicated by equation (2) and the definition of P'_i, participation serves to truncate the lower portion of the price distributions. Thus, if the distribution of net returns is normal under nonparticipation, it is likely not normal under participation.

Using equations (1) and (2), the participation decision of a field crop farmer in California's San Joaquin Valley was considered. A representative farm for Kern County was constructed with the following crop mix: 340 acres of wheat, 180 acres of barley, 80 acres of sorghum, 200 acres of cotton, and 120 acres of alfalfa hay.

In order to construct empirical probability distributions of net revenue, average Kern County prices and yields 1969–78 were used. While various government programs likely impacted on historical prices over this time period, the series of counterfactual prices would be difficult, if not impossible, to construct. Acknowledging this limitation, historical prices were used to construct the distributions. The probability distributions of prices and yields were considered independent. Empirical support or refutation for this assumption is difficult to obtain since farm level data are not available. However, support is indicated by low, and generally insignificant, correlation coefficients between prices and yields even at the county level.

Prices were deflated by the USDA index of prices paid for production expenses in order to adjust for inflation. The yield data were detrended with the following procedure. The data were regressed on time, and if the resulting coefficient was significant at the 5% level, the data were adjusted. The adjustment was made by predicting the mean value for 1979, and then adding to this value the regression residuals for each of the ten time periods. For the yield data, cotton and wheat required detrending. None of the deflated price data required detrending. Because one does not expect autocorrelated structures for yields, it was not deemed necessary to use an autoregressive, moving average scheme to detrend the data. Regression results are available from the authors upon request.

County check yields were used as program yields for wheat and feed grains in the calculations. The check yields are used by ASCS county committees as guidelines for determining program yields for individual farms. The check yields were obtained from the California state ASCS office. County check yields were not available for cotton because program yields are based solely on actual yields adjusted for abnormal conditions. A cotton program yield for the representative farm was calculated by applying ASCS formulas to the county average yield data.

Cost data were obtained from the University of California Cooperative Extension Budget Generator. The budget generator was used to synthesize costs for growing the various acreages of the five crops given above.

The upper and lower bounds on the risk aversion coefficients used in this analysis are shown in table 1. A negative value of $r(x)$ indicates risk proneness, a zero value indicates risk neutrality, and a positive value indicates risk aversion. Group 1 would include the most risk-preferring farmers, while group 12 would include the most risk-averse farmers. Little is known about farmers' risk characteristics, because very few utility functions

[4] Net revenue is multiplied by $(1 - S_i)$ to reflect the opportunity cost of the set-aside. If income-producing activities were allowed on the set-aside acreage, then the opportunity cost would have to be adjusted accordingly. However, under current provisions, no haying or growing of other crops is allowed on set-aside acreage. Also, this equation assumes that the participant's land is homogenous. If some of the land is of marginal quality, the opportunity cost would be reduced. Moreover, this equation does not consider all aspects of the participation decision, i.e., prevented plantings, diversion payments, use of nonrecourse loans for operating capital, and farmer-owned reserves. The farmer-owned reserves is a separate program beyond the scope of this study.

Table 1. Risk-Aversion Coefficients

Farmer Groups	$r_1(x)$[a]	$r_2(x)$[b]
Group 1	−0.04000	−0.03000

[b] Upper bound on the risk-aversion coefficient.

have been estimated for farmers (for a review of the measurement of farmers' risk preferences see Young et al.). The values in table 1 were selected so as to cover the range of risk-aversion coefficients reported in previous studies. If one assumes that the certainty equivalent is to surpass the lowest observation 90% of the time, then most decision makers would be in the lower portion of the risk-averse range (positive but close to zero) for constant risk-averse bounds and using most of the distributions studied. For this reason not all intervals were chosen to be of equal length.

The participation decision was analyzed by computing probability distributions of net returns for the representative farm based on the distributions of prices and yields, the synthesized cost data, and the 1979 target prices, loan rates, and set-asides. The program allocation factor was not known in advance by farmers, so the legislated minimum of 0.8 was used initially. The loan rate was assumed to truncate the price distribution in such a way as to stack all of the truncated probability at the loan rate. This is the truncation procedure used by Boehlje and Griffin. Target prices, loan rates, and costs also were deflated by the USDA index of prices paid for production expenses. The generated sample of net returns is given in table 2.

In order to assess the impact of program parameters on the participation decision, four alternative policy scenarios were examined. First, set-aside requirements were reduced by one-half. Second, target prices were increased 10%. Third, loan rates were increased 10%. Fourth, the program allocation factor was raised 10%. It was expected that each of these

Table 2. Generated Sample of Net Returns

1975	73,913	67,471	70,692	67,471	67,471	67,471	97,842	94,886	151,384	138,069
1976	88,470	82,379	85,499	84,582	82,379	82,394	129,538	126,744	180,542	167,930
1977	44,854	46,858	48,876	51,220	46,858	47,466	68,461	69,467	93,326	96,905
1978	17,245	20,511	21,983	24,088	20,511	20,766	16,627	23,876	38,324	44,361

Note: The empirical distributions were calculated in the standard way of associating with each sample point the probability of 1/10. This was done for the ten scenarios described below:

1. Nonparticipation
2. 1979 program features
3. Set-asides cut by ½
4. Target prices raised 10%
5. Loan rates raised 10%
6. Allocation factor raised 10%
7. Nonparticipation with different cropping pattern
8. 1979 program features with different cropping pattern
9. Nonparticipation with acreages of all crops doubled
10. 1979 program features with acreages of all crops doubled

Program parameters were obtained from ASCS. Cost data were calculated by the University of California Cooperative Extension Budget Generator. All yield data except alfalfa came from California Crop and Livestock Reporting Service (1977, 1979). Alfalfa yields came from Kern County Agricultural Commissioner. All U.S. price data came from U.S. Department of Agriculture. Kern County barley and wheat data were obtained from Federal-State Market News Service (a). Kern County alfalfa prices came from Federal-State Market News (b). Kern County cotton prices were obtained from Kern County Agricultural Commissioner. The figures given are in 1967 dollars.

four scenarios would increase the incentives for participation.

Once the probability distribution for a participant was computed, it was compared to the distribution of a nonparticipant using a program written by Meyer to implement his theoretical formulation. The participation distribution was compared to the nonparticipation distribution for each of the policy alternatives. In addition, Meyer's program was used to rank the probability distributions of net returns for nonparticipation versus participation for two different farming situations. In one case, the sensitivity of the results to the cropping pattern was examined by parameterizing the acreages. The acres of non-set-aside crops (cotton and alfalfa) were doubled, and the acres of set-aside crops were reduced in a proportional way so as to keep total acreage constant. The other case assessed the effects of farm scale by doubling the acreage of all crops.

Results

The results of comparing the probability distributions of net returns for a nonparticipant and a participant are shown in table 3. A "1" indicates that nonparticipation is preferred for the corresponding utility group. A "0" indicates that neither distribution dominates. A "−1" indicates that participation is preferred.

The entries in row 1 show the rankings for nonparticipation versus participation under 1979 program features. Within the risk-preferring range (utility groups 1–4), nonparticipation dominates for all of the groups. Within the risk-averse range (groups 5–12), the results indicate a mixture of participation and nonparticipation, with program participation preferred by the more risk-averse groups. As table 2 indicates, program participation reduces the probability of both high and low income events such that second degree stochastic dominance does not occur. Rows 2 and 3 of table 3 show that cutting set-asides or raising target prices increases the number of utility groups preferring participation since these changes reduce the probability of low income events. In both cases all risk averters choose to participate.

The impact of raising the loan rates, as shown in row 4, is surprising. The results indicate that fewer utility groups would choose to participate. This can be explained by a reexamination of equation (2). Notice that an increase in the loan rates has two contrasting effects on a program participant's net revenue. Raising the truncation level of the local market price distribution increases the mean of the probability distribution of per unit market revenue, P'_i. It also reduces the mean of the probability distribution of per unit deficiency payments, $TP_i - NP_i$, since the program defines NP_i as the higher of the national average market price or national loan rate. The results indicate that with the particular price distributions used in this analysis, the reduction in stochastic deficiency payments outweighs the increase in stochastic market revenues resulting from higher loan rates. Again, large and small outcomes are truncated by the program. In fact, the probability of falling below $85,000 is 1.0 under the program and only 0.8 with nonparticipation. However, raising the loan rate increases the likelihood of low incomes

Table 3. Stochastic Dominance Rankings

	Utility groups											
Nonparticipation versus:	1	2	3	4	5	6	7	8	9	10	11	12
1. 1979 program features	1	1	1	1	1	1	1	0	−1	−1	−1	−1
2. 50% cut in set-aside	1	1	0	−1	−1	−1	−1	−1	−1	−1	−1	−1
3. Target prices raised 10%	1	0	−1	−1	−1	−1	−1	−1	−1	−1	−1	−1
4. Loan rates raised 10%	1	1	1	1	1	1	1	1	1	1	0	−1
5. Allocation factor raised 10%	1	1	1	1	1	1	0	−1	−1	−1	−1	−1
6. 1979 program features and different cropping pattern	1	1	1	0	−1	−1	−1	−1	−1	−1	−1	−1
7. 1979 program features and doubled farm size	1	1	1	1	1	1	0	−1	−1	−1	−1	−1

Note: A "1" indicates nonparticipation is preferred and a "−1" indicates a preference for program participation. A "0" indicates that the group is not unanimous in its ranking; some would prefer participation while others would not. The rankings are for returns in thousands of dollars.

when comparing the 1979 program distribution with the distribution with an increased loan rate.

As noted above, the value of the allocation factor was not known in advance by farmers. It was legislated to be between 0.8 and 1.0, so the most conservative assumption of 0.8 was used in the preceding analysis. Clearly, the qualitative effect of raising the allocation factor is known a priori: participation becomes more attractive. In row 5 the quantitative effect of an increase in the allocation factor to 0.9 is that one additional utility group prefers participation. This higher value could reflect a legislated change or more optimistic expectations by decision makers.

Row 6 of table 3 shows the rankings of nonparticipation versus participation with a different mix of crop acreages. The acreages of cotton (a program crop with no set-aside requirement) and alfalfa were doubled, and the acreages of set-aside crops were reduced. With the lower opportunity cost of participation from less set-aside, four additional utility groups choose participation.

The effects of farm scale are demonstrated in row 7. In this case all acreages were doubled. In comparison with the smaller farm with the same crop proportions operating under 1979 program features (row 1), one additional utility group participates. As earlier, the program serves to reduce low and high income events. This makes the participation distribution function begin to the right of the nonparticipation function and possess greater slope. Because this reduces the evaluation of low probability events more than high probability events, risk averters find participation more attractive for the larger farm. This suggests that there may be greater participation incentives for larger farms.

To put these results in perspective, it is of interest to examine actual participation behavior. In 1979 the percentage of ASCS California acreage enrolled in wheat and feed grains programs was 16.0 as compared to a national figure of 38.9. (U.S. Department of Agriculture 1980). The breakdown by crop in California was 20.7 for wheat, 18.4 for barley, 6.3 for corn, and 5.2 for sorghum. There was no set-aside and no enrollment requirement for cotton. Clearly, a majority of the California acreage was not enrolled in the programs. This data, of course, pertains to a wider variety of farm situations than the representative farm used in this analysis. Rows 1, 6, and 7 of table 2, based on 1979 program features, indicate a mixture of participation and nonparticipation depending on individual risk attitudes. The relative proportion of farmers in the participating and nonparticipating groups cannot be determined, given the small number of individuals for whom risk preferences have been elicited. However, there is nothing in the results presented here that contradicts observed behavior.

Expected Utility and Mean-Variance Analysis

The mean, standard deviation, and skewness of net returns for the various acreages and program alternatives are shown in table 4. As can be seen, it would not be possible to use mean-variance efficiency analysis to rank the nonparticipation distribution (row 1) relative to the participation distribution (row 2) under the 1979 program for the representative farm. This is because participation would result in a lower mean as well as a lower variance. This result also holds for the representative farm under the higher loan rates and allocation factor, and for the larger-scale farm under the 1979 features. This yields support for the use of the more general framework, stochastic dominance, in efficiency analysis; i.e., probability distributions that cannot be ranked in a mean-variance framework can be ranked by stochastic dominance, and the quantitative effects of risk aversion can be studied.

For the other situations shown in table 4, program participation reduces the variance of returns as well as increases the mean. For these situations, if mean-variance analysis were conducted (e.g., assuming normality), the distributions could be ranked for risk averters (groups 5–12), but not for risk preferrers (groups 1–4).

Skewness values are reported in table 4. In every case the net returns' distributions are positively skewed, suggesting that the use of a symmetric distribution function, such as a normal one, may be inappropriate. Note, however, that the skewness measure in some cases is not altered greatly by program enrollment, cf. 1 and 2 of table 4. This is because, for some crop configurations, program enrollment eliminates both high and low returns in program crops in a symmetric fashion.

Although mean-variance efficiency analysis cannot be used to rank nonparticipation ver-

Table 4. Mean, Standard Deviation, and Skewness of Net Returns

Alternatives	Mean	Standard Deviation	Skewness
1. Nonparticipation	51,700	26,019	0.234
2. 1979 program	50,846	20,808	0.220
3. 50% cut in set-asides	53,845	21,596	0.239
4. Target prices raised 10%	54,906	18,926	0.134
5. Loan rates raised 10%	50,074	21,464	0.223
6. Allocation factor raised 10%	51,280	20,486	0.208
Alternative crop mix			
1. Nonparticipation	66,747	36,948	0.189
2. 1979 program	69,380	31,958	0.261
Larger-scale farm			
1. Nonparticipation	107,054	51,979	0.236
2. 1979 program	104,909	41,564	0.222

Note: Skewness calculations were computed with the following formula:

$$\frac{\left\{\left[\sum_{i=1}^{N} x_i^3 - 3\bar{x}\left(\sum_{i=1}^{N} x_i^2\right) + 3\bar{x}^2\left(\sum_{i=1}^{N} x_i\right)\right] \Big/ N\right\} - \bar{x}^3}{\left\{\left[\left(\sum_{i=1}^{N} x_i^2\right) - N\bar{x}^2\right] \Big/ (N-1)\right\}^{3/2}}$$

sus participation under 1979 program features, one can still use a Freund utility function (which assumes normality) to calculate the breakeven level of risk aversion for participation. This would be the degree of risk aversion at which a decision maker would be indifferent between enrolling or not under an assumption of normality of returns. The difference in expected utility between participation and nonparticipation can be expressed using the mean and standard deviation values of table 4. The difference set to zero can be solved for the breakeven level of risk aversion and compared with the more general analysis of table 3. Since the alternative crop mix comparison involves a relatively large change in skewness, it may yield a striking contrast. The breakeven based on Freund's function is found to be -0.0153; yet the results of table 3 suggest that the expected breakeven point is in the interval $(-0.01, 0)$. Given the orders of magnitude usually thought of for $r(x)$, this represents a considerable difference. This serves to caution use of mean-variance analysis and indicates that crop mixtures may substantively alter the family of the distribution of returns and the implied indifference point between choices.

Conclusion

Using historical data, this analysis shows that risk attitudes may affect the participation decision; however, subjective beliefs also are important. Subjective probability distributions vary widely across farmers. Results from analysis based on elicited subjective distributions not reported here indicate that participation choices are quite sensitive to farmers' expectations; those who are more pessimistic about prices and yields are more likely to participate. The distribution of participation choices among farmers will depend jointly on their subjective probabilities and risk attitudes. In this analysis, historical prices and yields have been used, because it is hoped that even with aggregation errors they represent the central tendency of aggregated subjective distributions.

It is always difficult when using the representative farm approach to ascribe the results to a wider group; what has been presented is not presumed to represent the choices of all California or even all Kern County farmers. Rather, the intent has been to illustrate how changes in program parameters can affect program participation decisions, given varying attitudes toward risk. For example, increasing the loan rate, *ceteris paribus*, suggests fewer program participants.

This analysis shows that stochastic dominance is a useful method for analyzing the impacts of policy changes on program choice and for aiding in decision making at the micro level. Extension personnel could easily adapt

the model to specific farm situations by inserting relevant crop acreages, cost figures, and subjective probabilities on prices and yields as a natural generalization of computer-budgeting procedures. Given a rough estimate of risk preferences (for example, using the modified von Neumann-Morgenstern reference contract approach, which can be measured easily by lotteries on cassette), the approach here could delineate the efficient choice for an individual. Hence, stochastic dominance needs further consideration as a practical and inexpensive tool for decision making under uncertainty at the farm level.

Notes

The Land Grant Colleges and the Structure Issue

Don Paarlberg

Recent writers have documented the fact that American agriculture is becoming industrialized. The earlier delineation into farm and nonfarm sectors is being blurred. Agriculture is losing its uniqueness; farmers are entering the main stream of economic, social, and political life. The agrarian tradition is in retreat. The family farm as an earlier generation knew it is rapidly vanishing. Numerous writings quantify these trends; for examples, see Lewis, Lin, Madden, Miller, Penn, Schertz, Senate Committee on Agriculture, University of Illinois, and U.S. Congress.

Some people look at these trends as being, on balance, good. Others consider them to be bad. Still others think of them as a mixture of good and bad. There is a division of opinion as to whether the trends are inexorable or whether they might be changed by public policy. Thus has arisen what has become known as "the structure issue."

The issue was lifted up by what became known as the "Hard Tomatoes Report" (Hightower). This publication alleged that the Land Grant College system had become subservient to agribusiness concerns. Various activist groups expressed concern about the deportment of the Land Grant Colleges, alleging that they showed preference for the large farmers. There were also charges with respect to environmental concerns, consumer issues, and the like. In 1979, Secretary Bergland brought matters to a head with a "dialogue on farm structure," a series of public hearings throughout the country.

For the purpose of this article, J. B. Penn's definition of structure is accepted. According to Penn, structure involves the following components: organization of resources into farming units; size, management, and operation of these units; form of business organization, whether a sole proprietor or several individuals in a partnership or corporation; the degree of freedom to make business decisions; the degree of risk borne by the operator; the manner in which the firm procures its inputs and markets its outputs; the extent of ownership and control of resources that comprise the farming unit; the ease of entry into farming as an occupation; and the manner of asset transfer to succeeding generations.

The structure issue presents the Land Grant College system with unsought and difficult questions. What has been their role in the emergence of these trends? How should they position themselves with regard to the current and prospective dialogue on these matters?

The thesis of this article is that the Land Grant Colleges, with their experiment stations, their extension services, and their classroom teaching, are operating to a considerable degree on the basis of two assumptions—implicit rather than explicit—made many years ago; that these assumptions have been called into question by the dialogue on structure; and that the Land Grant College system will have to reconsider these assumptions and decide whether to defend or revise them.

The two implicit assumptions are:

(a) that research and education are structurally neutral, and

(b) that technology is socially neutral.

These assumptions of neutrality are not embraced universally within the Land Grant College system, of course, but they are accepted widely enough so that they have contributed strongly to rhetoric and policy. The assumptions go back a long way and carry up to modern times. They are evident in the mood and tone of the report submitted by the Commission on Country Life, a seminal work. They are implicit in *A National Program of Research for Agriculture* (USDA-NASULGC) and in *Inventory of Agricultural Research, FY 1969–70* (USDA 1970). The Extension Service reflects these implicit assump-

tions. Witness, *A People and a Spirit* (Colorado State University 1976) and *Extension's Commitment to People* (Vines and Anderson). The Extension Service recently modified somewhat its assumption of social and structural neutrality in its publication *Evaluation of Economic and Social Consequences of Cooperative Extension Programs* (USDA 1980). That the Land Grant Colleges have been reluctant to see the structure question raised is evidenced by their lack of enthusiasm for the national dialogue on this issue.

The assumptions that the consequences flowing from research and education were technical and economic rather than structural or social had considerable validity—and credibility—when they were first embraced 100 years ago. But, as the transformation of agriculture has proceeded, both their relevance and their acceptance have eroded. I propose to examine each of these implied assumptions, its validity, and its amenability to change.

Are Research and Education Structurally Neutral?

The Land Grant Colleges are a product of agrarian philosophy, which postulated the family farm as a uniquely valuable institution. The original intent was to make the family farm more efficient and thus more profitable. Research and education were the chosen means by which to achieve this objective.

Beyond doubt, the research and educational activities of the Land Grant College system were instrumental in helping make American agriculture the most efficient food producer the world has ever seen. In 100 years farming advanced from its traditional pattern to its present highly sophisticated form. The food supply increased in volume, improved in variety, and diminished in relative cost. Benefits were shared among various sectors of the society. Earl Heady has said: "The United States has had the best, the most logical, and the most successful program of agricultural development anywhere in the world" (p. 107).

That research and education might have the long-run effect of helping transform agriculture into something like an industrial enterprise was not envisioned by those who founded the Land Grant College system. But this is indeed what happened. Responsibility for this transformation must be shared, of course. Involved were not only publicly supported research and education, but privately supported initiatives of this same kind, plus farmer decisions, agribusiness ventures, and government programs of various types.

As the nature of modern agriculture began to emerge, the Land Grant Colleges found themselves in a dilemma. What was their position on structural change? What were they trying to do? Were they trying to preserve the traditional family farm? Were they trying to make agriculture over in accordance with an industrial pattern? Public espousal of either of these two positions would be dangerous. Preservation of the family farm in anything like its original form would mean shutting down most of the experimental and educational activity and jeopardizing the food supply. On the other hand, frank endorsement of an industrialized agriculture would imperil traditional support.

So, understandably, the Land Grant College system implied that it was structurally neutral. In their publications and in their appeals for funds, the research and education people confined themselves to technical and economic matters. The profound structural and social changes which agriculture was experiencing were presumed to have other origins. The posture was essentially this: The business of the Land Grant College system was to help farm people improve their methods so as to become more efficient, a noncontroversial criterion conveniently endorsed by the economists. Research and education were offered to all who would respond. The mission was to improve technology, not to set up and pursue some idealized structural design. The emphasis was on microeffects; concerns for macroeffects were largely adjourned. Whatever structural pattern evolved from this setting was natural and unintended. In Nietzsche's phrase, it was "beyond good and evil."

This posture had credibility for the better part of a century. It served to screen off the Land Grant College system from ideological contention and from political battles. It helped induce farmers to accept individual responsibility for such good and bad experiences as they encountered.

But evidence has come before us that the Land Grant College system, whatever its intent has served to speed the trend toward an industrialized agriculture. It simply has not been possible to make such great advances in efficiency as have occurred without having profound effect on the structure of agriculture.

The experiment stations, by conquering poultry disease, made it possible to grow thousands of birds in close confinement, thus transforming the broiler industry. The Extension Service, with its advice that a farmer should have a business "big enough to be efficient" undoubtedly speeded up farm consolidation and reduced the number of farms. In the classroom, emphasis on modern management helped put the traditional family farm into a state of near-total eclipse.

Medium and large farm operators have more contact with extension programs than do small farmers (USDA Jan. 1980, p. viii). What happens is this: the research and extension people make their offerings available to all, cafeteria style. The farmers who avail themselves of this help are generally the more alert, the more innovative, the more aggressive, the more politically astute, the socially dominant, the better managers of the larger farms. They select what is useful to them, in their circumstances. In the next round the research and education people, like good cafeteria managers, supply more of what moved best and less of what moved poorly. So, over time and without deliberate intent, the offerings are tilted toward the bigger, better, wealthier, and more innovative farmers. After several such rounds, even if the small farmer should come to the extension meeting, he would find little of value to him. The clientele is self-selected. There is no conspiracy, but the results are not greatly different from what they would be if there were. Thus, public-supported research and education accelerate the trend toward the industrialization of the food system and widen the income differentials within agriculture.

Supporters of research and extension contend that while the big operators are generally the early adopters, there is a "filter-down" effect; in time the smaller operators emulate the big ones. In earlier years, when agriculture was more homogenous, the "filter-down" effect no doubt was stronger than it is at present. For example, 40% of the hogs are now produced by year-round, low labor, capital-intensive confinement units selling more than 1,000 hogs annually. Among hog producers, they are the chief users of research and extension. Practices in use on such farms have limited applicability for farmers producing smaller numbers of hogs by traditional methods on a seasonal basis.

The side effects of research and education in agriculture are now being held up for examination. Most of the activists allege that the side effects are on balance adverse, but this has not been established.

In positioning itself with regard to this issue, the Land Grant College system faces a choice among alternatives:

(*a*) Leave the programs essentially unchanged while continuing to imply that research and education are structurally neutral. This is the wish of the larger farmers, who are the agricultural elite. But this posture becomes increasingly difficult to defend with passing time.

(*b*) Continue the programs much as they are and drop the facade that they are structurally neutral. Acknowledge that the Land Grant College System serves the needs of the better, bigger farmers and accelerates the trend toward an industrialized agriculture. Frankness argues for this; political expediency argues against it.

(*c*) Revise the programs so that they come closer to being structurally neutral, as is professed. Modify agricultural research, extension, and classroom teaching so as better to serve the needs of small, moderate-sized and part-time farmers. This appears to be the objective of those who raise the structure issue. But it is hard to do and is offensive to the agricultural elite.

(*d*) Some combination of the above.

One can readily sympathize with the Land Grant Colleges in having their facade of structural neutrality stripped away and being forced into so difficult a choice.

With a growing share of agricultural research and education now being provided privately or through nontraditional institutions, and with the trends toward industrialized agriculture having built up such great momentum, the choice among the alternatives may have more relevance to the structure of the Land Grant College system than to the structure of agriculture.

Is Technology Socially Neutral?

The Land Grant Colleges convey the inference that they are not only neutral with respect to the structure of agriculture; they also think of themselves as socially neutral. That is, they generally profess to be impartial in their service to various groups of farmers and they like to think that their activities do not basically alter the established relationships among

different individuals or groups in the society. They are staffed by scientists and technologists who work on improved methods of producing, processing, transporting, and merchandising food and fiber. The staffers contend that the primary result of their work is to improve efficiency without altering prevailing social or political patterns. Their graphic model of the relationship of advances in agriculture efficiency to the general benefit of the public is a line that is positive, linear, and steep. An efficiency gain is good, a larger gain is better, and the greatest gain that could be achieved would result in the greatest possible public benefit. In the conceptual models, social and political consequences of technological advance are impounded in "other things equal," or are labeled "side effects" and "externalities." Sometimes, of course, the conceptual model of social sterility is set aside to accept credit for a social development deemed worthy like the improved status for farm people, which undoubtedly has resulted from educational services provided by the system. But rarely is responsibility acknowledged for social developments that have a bad connotation. This straddle involves some difficulties, like taking credit for the hog but not the smell.

The assumption—implied rather than explicit—that technology is socially neutral has permitted the Land Grant College system to concentrate on its intended purpose, technological change. The socially elite have not felt threatened and the politically powerful have felt secure. Having thus reassured the establishment, the Land Grant College system was free to do its work with a minimum of harrassment.

But the evidence being lifted up by the dialogue on structure is that technology is not neutral. The modernization of cotton production in the South, in large part a result of work done by the Land Grant Colleges, displaced millions of people. Many of these people migrated to Chicago, Detroit, Cleveland, Washington, and New York, to a culture they understood poorly, in search of jobs for which they were not prepared. At least in the short run this was a difficult transition. Perhaps in the long run it will prove advantageous. This "side-effect," whether on balance good or bad, exceeded in significance the cost-lowering achievement of the research and education on cotton production, in my view.

The voluntary nature of the research and educational system resulted in nonservice to those who lacked the sophistication, the social status, and the political clout to obtain such service. The cost-lowering production-increasing practices adopted by the innovators reduced prices of farm products and put pressure on those who for various reasons could not or would not, or in any case did not, employ the new techniques. Many of these people and their children left agriculture. Undeniably, this had social consequences.

When the Land Grant College system was set up in 1862, 59% of our people were on farms. In part as a result of research and education supplied by the system, farms were enlarged and reduced in number, so that farmers now constitute less than 4% of the population. T. W. Schultz puts the actual outmigration from American farms during the years between 1930 and 1974 at 33 million people, the largest migration of modern times. One can argue at length as to whether so massive a change is good or bad. But it is not possible to argue convincingly that transformation from an agrarian to an industrial society is socially neutral.

Research has shown that the modernization of agriculture can have adverse effects on the social structure of rural towns and villages (Community Services Task Force Report). Other research has shown the pervasive social benefits of efficient food production (Heady).

The graphic model that describes the relationship of agricultural efficiency to the benefit of the public may not be positive, linear, and steep, as the Land Grant Colleges generally assume it to be. Instead, it may be a curve, reaching its apogee at some point short of imposing intolerable stress on the social fabric. Beyond that optimum point the curve may turn down, and if the pursuit of efficiency is carried too far, it may become negative. "Side-effects" may break out of the stockade within which assumption has sought to impound them. This is the model of the sociologist, the anthropologist, and the political scientist. These people are almost without representation in the Land Grant College system.

Whether there is such a curve and, if so, where we are on it are debatable subjects. But the assumption that technology is socially neutral is increasingly hard to defend. Who will deny that farm people were elevated socially when, through the Land Grant College system, their opportunities were increased? Who will contend that the outmigration from ag-

riculture of 33 million people was without social significance?

The most vivid examples of the nonneutrality of agricultural research and education, socially speaking, are to be found in overseas developmental programs. The surge of rural populations to the great cities, in part the result of agricultural development, is perhaps the most persuasive evidence that agricultural technology has social consequences. Agricultural development, based on research and education, is one of the most potent of social transformers. Whether the transformation is for good or evil depends on its components, its magnitude, its speed, its duration, and the manner in which it is perceived.

The alternatives facing the Land Grant College system regarding the social consequences of its programs are similar to those related to farm structure: (*a*) continue to imply that technology is socially neutral; (*b*) continue the existing programs and frankly acknowledge that they have social consequences, good and bad; (*c*) modify the existing programs, taking into account their social consequences; or (*d*) a mixture of the three.

The third alternative would involve changes in research. Some of the variables would be shifted from exogenous to endogenous form. Some "externalities" and "side-effects" would be moved into the model. Macro as well as micro forces would be taken into account. Some sociologists might be employed. We are beginning to do this for our overseas agricultural development programs, but have some difficulties in bringing ourselves to it for our own country.

Changes in the extension program also would occur. The present tilt in favor of the larger farms and high technology would be reduced. In a voluntary program, lacking central direction, it probably cannot be eliminated. Favorable social consequences of research and extension would be documented, and work would be expanded in these areas. Some resources would be directed to alleviating the adverse side effects of certain research and educational programs.

This would all be difficult. It would involve discarding the defensive armor that has, for 100 years, kept the Land Grant College system reasonably well-insulated from social and political strife. It would involve modifying the assumption that efficiency, in a micro sense, should be the decisive if not the sole criterion for agricultural change.

But the defensive armor is losing its effectiveness. The old postulates can no longer be insulated from those who question them. There may be no real alternative to revising the assumptions. If this is done, quite possibly the Land Grant Colleges would come, in time, to be pleased with the result. On the basis of newer and broader criteria, their programs might improve, and balanced public assessment of their net structural and social effect might well turn out to be positive. The Land Grant Colleges may have less to fear than they imagine.

Composite Forecasting: An Application with U.S. Hog Prices

Jon A. Brandt and David A. Bessler

Producers, processors, and distributors of agricultural commodities make decisions in a risky environment. Uncertain production and relatively low price elasticities of demand provide the setting for rather large fluctuations in commodity prices. Sensible decision making thus requires information about the likelihood of many alternative outcomes. Such information can be obtained from both private and public sources through price forecasts.

Decision makers often have several forecasts on which to base their plans. They realize that alternative forecasting systems rarely give the same forecast. When faced with alternative forecasts of the same event, it is quite typical to attempt to discover which forecast is best. For example, Leuthold et al. considered alternative approaches to forecasting daily hog prices—time-series [autoregressive integrated moving average (ARIMA)] and econometric models. They concluded that the econometric model did slightly better than the ARIMA model over the evaluation period. At first glance, one might conclude that it is better to use the econometric model and refrain from using the ARIMA model. However, further study probably would reveal that each set of forecasts contains useful information which the other does not possess.

Indeed, this is the case illustrated in a study by Bates and Granger, where they considered two alternative models for forecasting monthly airline passenger mileage. While one of the models showed an overall superiority, their combined forecasts outperformed both individual forecasts. In fact, for an optimal combination of individual forecasts, it can be demonstrated that the combined forecasts will have an error variance not greater than the smallest error variance of the individual forecasts. Additional theoretical and empirical analysis by Johnson and Rausser, Granger and Newbold, and others have confirmed and extended the early efforts of Bates and Granger.

Forecasting Techniques

The justification for and empirical accuracy of several composite forecasting techniques based on the individual forecasts of econometric, ARIMA, and expert opinion methods are examined in this study. This will be accomplished, in part, by empirically evaluating the quarterly U.S. price forecasts for hogs through selected measures of performance. From these evaluations, forecasters and forecast users should have a clearer understanding of some of the advantages and limitations of individual and composite model forecasting.

Individual Models

Our objective was to develop an econometric price forecasting model for hogs which was relatively accurate and simple to understand, use, and update.[1] Consequently, a single-equation reduced-form model was formulated which included lagged supply and demand variables (with the exception of current income) that explained (predicted) movements in prices.[2] The following equation was estimated using ordinary least squares regression over the sixty-quarter period from 1961 through 1975:

$$(1)\quad \begin{aligned} PH_t = &-172.5056 - \underset{(11.14)}{8.5038}SF_{t-2} \\ &- \underset{(5.21)}{3.8707}SF_{t-3} - \underset{(4.99)}{3.9388}CS_{t-1} \\ &- \underset{(5.71)}{42.6470}HTCH_{t-1} + \underset{(16.76)}{47.5997}\ln Y_t \\ &- \underset{(7.30)}{44.7532}PKST_{t-1}, \end{aligned}$$

where $R^2 = .93$, $D.W. = 1.79$, PH is the quarterly weighted farm price of hogs, SF is the number of sows farrowing quarterly in fourteen states (millions), CS is U.S. commercial cattle slaughter (billion pounds), $HTCH$ is quarterly broiler-type poul-

Jon A. Brandt and David A. Bessler are assistant professors in the Department of Agricultural Economics, Purdue Univerty.

Journal Paper No. 8098 of the Agricultural Experiment Station, Purdue University.

The authors wish to thank the departmental Marketing Guides and Outlook Committee for providing the expert opinion information used for this study, John Ikerd, and an anonymous reviewer for suggestions on an earlier draft of this article.

[1] Crowder and Cromarty and Myers have argued that a significant gap exists between the theoretical group of model builders and the user group who seek simplicity and judgment in solving problems. Chen, however, has suggested that this gap has been narrowing. In this analysis, simplicity and theoretical soundness were concurrent goals.

[2] Econometric models often have used current endogenous and current exogenous variables as regressands. This suggests that the forecaster must also generate predictions for the explanatory as well as the dependent variable. Such a procedure is likely to compound the forecasting errors. However, because income has been trending upward rather steadily, it was felt that little error would result in projecting its movement.

try eggs hatched (billion eggs), $\ln Y$ is the natural logarithm of quarterly disposable income (billion dollars), $PKST$ is pork cold (and cured) storage at the end of the quarter (billion pounds), and t reflects the quarterly period of observation. The figures in parentheses are the t-values of the coefficients. It appears that the single-equation model has performed reasonably well in explaining price movements. All coefficients are more than twice their standard errors. These coefficients were used to make the initial forecast for the first quarter of 1976 (7601).[3]

As an alternative to the structural econometric model, forecasts are possible by specifying prices as autoregressive integrated-moving-average (ARIMA) processes. Box and Jenkins suggest a three-step procedure for identifying the class of ARIMA models, estimating the parameter values of the identified model, and checking the appropriateness of the estimated model.

The identification procedures involve the comparisons of estimated autocorrelations and partial autocorrelations of the series of interest with the theoretical autocorrelation and partial autocorrelation functions of known ARIMA processes. Given a class of ARIMA models from the first stage, their parameter values can be estimated from the historical series using nonlinear least squares. Finally, the identified and estimated model can be checked by studying the behavior of the residuals.

These procedures were applied to the quarterly hog price series, resulting in the following ARIMA model:

$$(2) \qquad (1 - B)PH_t = (1 - .44B^5)e_t,$$

where B is the lag operator ($B^i PH_t = PH_{t-i}$) and e_t is a white-noise random disturbance. The chi-squared statistic associated with the estimated residuals of this model is well under the critical value at the 5% level of significance, which does not lead us to suspect the adequacy of the estimated model.

Another alternative to the quantitative models suggested above is expert opinion prediction. Universities, the U.S. Department of Agriculture, private forecasting firms, and others routinely generate forecasts. These are usually short-run in nature and are based on an understanding of the industry structure, seasonal production and consumption patterns, and international events that affect the commodity. In many respects, the forecasts of experts are like those of econometric or ARIMA model forecasts in that they incorporate information from similar data sources. Expert opinions, however, are less restrictive because the weights assigned to different bits of information can be changed with relative ease.

[3] The model was designed to allow for continuous update. Thus, new coefficients were estimated each quarter as new data became available. The magnitudes of these coefficients did not vary much from quarter to quarter, however.

Composite Models

Following Bates and Granger, one can recognize that most forecasts contain some information which is independent of that contained in other forecasts. Thus, a combination of forecasts will, quite often, outperform any of the individual forecasts. For convenience, the discussion here is limited to unbiased forecasts. Detecting and combining biased forecasts is discussed in another paper by the authors.

Three approaches used to combine the forecasts of the individual models described above are summarized here. (See Bessler and Brandt for more detailed development of these methods.) These involve different methods for choosing the weights assigned to each individual forecast. Two of the methods require an historical record of performance by the forecasting models. The first is a weighting scheme based on the sixty-quarter historical forecast period prior to 7601. The approach assumes the performance of each individual forecast method is consistent over the forecast period. Combining the forecasts of two methods results in the following weights:

$$(3) \qquad a_1 = \frac{\sigma_2^2 - \rho_{12}\sigma_1\sigma_2}{\sigma_1^2 + \sigma_2^2 - 2\rho_{12}\sigma_1\sigma_2}$$

$$a_2 = 1 - a_1,$$

where a_i is the weight assigned to forecast method i, σ_i^2 is the forecast error variance associated with method i, and ρ_{ij} is the correlation coefficient between the errors of forecasts i and j. This weighting scheme minimizes the variance of the forecast errors over the sixty-quarter historical period.

A second method involves an adaptive weighting scheme which allows the weights to adapt or change from period to period. It is based on the assumption that forecasting models may not have constant performance over time. Thus, weights can be constructed which reflect recent forecast errors more strongly than distant ones. The following expression can be used to determine weights for two forecast methods:

$$(4) \qquad a_{1,T+1} = \sum_{t=T-v}^{T} \frac{e_{2t}^2}{e_{1t}^2 + e_{2t}^2}$$

$$a_{2,T+1} = 1 - a_{1,T+1},$$

where $a_{1,T+1}$ is the weight assigned to forecast method 1 in period $T + 1$, e_{it} is the error made by forecast method i in period t, v is the choice variable which represents the number of periods included in the adaptive weighting procedure, and T is the total number of periods for which a history of forecast errors is available. Thus, only the errors for the last v periods are considered when assigning weights.

A third, rather simple, method for combining forecasts is simple averaging. Often, a user has several forecasts available but does not have a his-

tory of performance on each. Rather than arbitrarily basing decisions on one particular forecast, the user can combine all forecasts by averaging. This gives each forecast equal weight and involves relatively low calculation costs.

Forecast Results and Performance Evaluation

Individual Model Forecasts

Hog price forecasts were generated by each of the three individual methods over the fourteen-quarter period 7601 through 7902. These forecasts (and their associated mean-squared errors) presented in columns 2, 3, and 4 of table 1 can be compared with the actual prices in column 1. While this is not a long period over which to evaluate the performance of the forecasting techniques, it does serve as a starting point from which further updating and evaluation can be performed as new observations become available. In addition, these fourteen periods do provide a sufficient sample over which to generate composite forecasts.

The mean-squared error results suggest that among the individual methods, the ARIMA model performed substantially better than either the econometric or the expert opinion. In each of these latter two methods, a single, poor forecast (in 7604 for econometric and 7801 for expert opinion) sharply increased the mean-squared error statistics.

Table 2 indicates the accuracy of the models in tracking the movements of actual prices from period to period by cross-comparing the predictions of the forecast models with actual observations. If prices increased one period, then decreased the next, a change in the direction would be observed. Price increases two periods in a row suggest no change in direction. If an actual change were correctly forecast, the upper left-hand element in each 2×2 matrix would be increased. Similarly, if no change were predicted and observed, the lower right-hand element would be incremented. High numbers in these diagonal elements are indicative of high performance by the models. High off-diagonal numbers are indicative of poor performance.

The econometric model did a poor job in tracking the hog price series. In eight of the periods, the model predicted a change in the direction of the series when, in fact, none occurred. In only four of the periods did the econometric model correctly predict a change in the series. For the ARIMA and expert-opinion models, the tracking performances for the hog price series were considerably better. Both models accurately tracked the price movements in more than half of the quarters.

Composite Model Forecasts

Three methods of combining the forecasts of the individual econometric, ARIMA, and expert-opinion techniques are analyzed in this section. One approach incorporates the adaptive process [equation (4)] whereby the weights assigned to each

Table 2. Turning Point Measures for Evaluating Individual and Composite Model Forecasts

Movements		Individual Models					
		Econometric		ARIMA		Expert Opinion	
		C	NC	C	NC	C	NC
Actual	C	4	2	4	2	4	2
	NC	8	0	3	5	4	4

		Composite Models[a]							
		Two-period Adaptive[b]		Minimum Variance[b]		Simple Average[b]		Simple Average[c]	
		C	NC	C	NC	C	NC	C	NC
Actual	C	3	2	3	2	2	3	3	2
	NC	3	4	2	5	3	4	4	3

Note: The measures indicate a change (C) or no change (NC) in the direction of the price movement, i.e., a prediction of turning points. Higher performance is associated with larger numbers on the positive diagonal of each 2 × 2 matrix.
[a] Because only fourteen expert-opinion forecasts were available, only twelve between-period comparisons were possible.
[b] Composite of econometric and ARIMA methods.
[c] Composite of econometric, ARIMA, and expert-opinion methods.

model vary over time, depending on the accuracy of the model over previous periods.[4] The second method combines forecasts based on a minimum variance criterion [equation (3)]. The third method averages the forecasts of the methods for each period (equal weight to each model).

The composite results based on the three methods of combining the forecasts of the individual techniques over the fourteen-quarter period, 7601–7902, are also presented in table 1. The adaptive (column 5) and minimum variance (column 6) processes used in weighting the forecasts require a history of predictions. Expert opinion forecasts prior to the 7601–7902 period were not available. Therefore, the adaptive and the minimum variance forecasts are a composite of only the econometric and ARIMA models. For comparison purposes, simple-average forecasts of these two methods are presented in column 7. Finally, composite forecasts using a simple average of all three techniques (econometric, ARIMA, and expert-opinion) are provided in column 8.

The adaptive-process forecasts are those which resulted in the minimum mean-squared error [for $\nu = 1, 2, \ldots, 60$ in equation (4)]. Combining the predictions of the econometric and ARIMA models of the two prior periods (i.e., $\nu = 2$) to determine the weights for the current forecast period generated the smallest mean-squared error of the sixty processes analyzed. The weights associated with the price forecasts from the adaptive process reflect this short error history. The actual weights assigned by the process to the econometric forecasts range from a high of .98 to a low of .01. [In examining two other livestock commodities in the study, the authors found a similar range of weights for the econometric method for cattle price forecasting, based on only a single prior period's errors ($\nu = 1$). In contrast, a more stable behavior of adaptive weights was noted in forecasting broiler prices, where an error history of nine periods generated the lowest mean-squared error (Bessler and Brandt).]

A comparison of the composite forecasts with those from the individual forecasting methods suggests that the MSE's from the three-method simple-average and the minimum variance method are slightly lower than the ARIMA MSE (table 1). Each mean-squared error of the composite forecasting methods is considerably lower than that of either the econometric or the expert opinion method. From the theoretical concepts supporting the composite forecasting approach, it would be expected that if two (or more) forecasting techniques were based on different information, the quality (MSE) of the forecast should be improved by combining them. The MSE performance criterion is consistent with this hypothesis.

Table 2 illustrates the ability of the composite forecasts to track the actual price movements. The composite forecasts accurately predicted the direction of the price movements in at least half of the periods. The results in table 2 suggest that the composite methods perform about the same as the individual methods for tracking price movements.

Perhaps the most significant argument that could be made for considering composite forecasts is that none of the composite forecasts performed as poorly as the worst of the individual techniques. This is particularly important to the user who has several sources of forecasts available to him. If the user has reason to believe that each is based on sound information and has no prior knowledge concerning its performance, he might select any of the three techniques and base his production and marketing plans on the forecasts of that particular

[4] The smallest number of observations (i.e., previous forecasts) used to generate weights was one; the largest number was sixty. In all cases, as a period was added, the most distant period was deleted.

method. Consequently, the user might accept unusually high risk if he based his plans on an inferior forecasting technique. The composite forecasts do not exhibit this same pattern. The mean-squared error of the best composite method (simple average of all methods) is only 86% of the mean-squared error of the best individual method (ARIMA). The MSE is the poorest of the composite methods (simple average of econometric and ARIMA models) is 50% of the MSE of the poorest individual method (expert opinion). Furthermore, if one does not know which set of forecasts to use based on a priori information, the riskiness of a large mistake is reduced by selecting the composite set.

Closer inspection of table 1 indicates that the mean-squared errors from the somewhat more sophisticated composite weighting schemes (adaptive and minimum variance) are lower than that of the simple average composite of the econometric and ARIMA models. This example shows that if a history of forecast performance of the models is available, the incorporation of this information through the weighting procedure can result in greater accuracy of the composite forecasts. However, note that as additional information is added to the set (in the form of expert opinions), the mean-squared error is reduced further (column 8).

Implications: Forecast Users

The analysis performed in this article has several implications to users of price forecasts. (*a*) Forecasts taken strictly from individual models are not likely to provide the user with the most accurate information for decision making. It was shown that large errors are likely in each of these models. (*b*) Even if the user has no prior performance record of the forecasting models, he might be advised to combine the forecasts from alternative models in a simple fashion (such as averaging) to remove the likelihood of making large mistakes based on the forecasts of a single model. (*c*) If prior forecasting performances of the models are available, the user could weight future forecasts of the alternative methods based on this past record. He will want to pay close attention to the relative performance of each model. Elsewhere the authors show that incorporating the prior performance of the individual model's forecasts, either through the minimum variance or adaptive process weighting schemes, results in lower mean-squared errors than those from simple averaging of price forecasts. A word of caution is suggested for users, however. Forecasts in this study were for a rather short period (fourteen quarters).

Forecasters

The results of the performance evaluation suggest that forecasters should seriously consider using composite forecasting techniques. The idea that alternative forecasting methods use a variety of different information sources and means for assimilating the information and generating forecasting is theoretically appealing. Empirically, the results of this study agree with those of earlier researchers confirming the usefulness of composite forecasting. It might be beneficial to both users and other forecasters to know if the forecasts available from various sources are composites or based on a single method.

Forecasting models must be evaluated in order for both the forecaster and the user to have confidence in the forecast. Alternative performance criteria were used to measure the performance of individual and composite models for forecasting hog prices over a fourteen-quarter period. The results of these measures might be compared with the accuracy of other forecasts made by other groups. The work reported in this note provides additional empirical evidence on composite forecasting—evidence which should be set alongside that of earlier studies (and those which may follow) to evaluate the usefulness of composite forecasting with empirical data.

On Variances of Conditional Linear Least-Squares Search Parameter Estimates

Edmund A. Estes, Leroy L. Blakeslee, and Ron C. Mittelhammer

Among the class of models that are nonlinear in the parameters, some lend themselves to a simple estimation method requiring repeated application of linear least squares. However, there is confusion over methods for computing standard errors of such estimates.

In this paper we define a simple method for estimating parameters of certain nonlinear models and clarify the interpretation of results. This method is based on conditional linear least squares. It has been used by Just (1974a,b, 1977) to estimate a generalized adaptive-expectations supply model. We show that a method commonly used to estimate asymptotic standard errors of such parameter estimates systematically overstates precision. Factors that affect the degree of overstatement are delineated. A method of calculating correct precision measures is contrasted empirically with the incorrect procedure.

Conditional Linear Least Squares

A wide range of stochastic models used in applied research can be written in the form

$$(1) \qquad Y_t = F(X_{t1}, X_{t2}, \ldots, X_{tk}; \beta) + U_t.$$

It is assumed that the disturbances in (1) are independently and identically distributed normal random variables, and, under this assumption, nonlinear squares and maximum likelihood procedures applied to estimate β in (1) are equivalent. Note that the natural logarithm of the likelihood function associated with (1) takes the form

$$(2) \quad \ln L(\beta, \sigma^2) = -\frac{n}{2}\ln 2\pi - \frac{n}{2}\ln \sigma^2 - \frac{1}{2\sigma^2}\sum_{t=1}^{n}[Y_t - F(X_{t1}, \ldots, X_{tk}; \beta)]^2,$$

so that for any $\sigma^2 > 0$, ln L is maximized when β is chosen to minimize the residual sum of squares,

$$\sum_{t=1}^{n}[Y_t - F(X_{t1}, \ldots, X_{tk}; \beta)]^2.$$

In practice the maximum likelihood estimator $\bar{\beta}$ can be found either by solving a set of nonlinear normal equations or by using a search algorithm. In certain important applications the function F will have a form so that conditional on values of $p < m$ of the m parameters in the β vector, and on the X's, the function is linear in the remaining parameters.

Notable examples of models that have this property include the model that results from a Box-Cox power transformation of explanatory variables as

$$(3) \quad Y_t = \beta_0 + \beta_1(X_1^\lambda - 1)/\lambda + \ldots + \beta_K(X_K^\lambda - 1)/\lambda + U_t.$$

Note that (3) is linear in its parameters, given $\lambda = \beta_{k+1}$. The constant elasticity of likelihood (CES) production function, equation (4), is a second example.

$$(4) \quad Y_t = \beta_0[\beta_1 K_t^{-\beta_2} + (1 - \beta_1)L_t^{-\beta_2}]^{-\beta_3/\beta_2} e^{u_t}.$$

After logarithmic transformation it is linear in β_3 and ln β_0 if β_1 and β_2 are given. Just's (1974a,b, 1977) generalized adaptive expectations model is a third example. In its basic form, it can be written as

$$(5) \quad Y_t = \beta_0 + \beta_1 P_{t-1}^e(\beta_3) + \beta_2 V_{t-1}^e(\beta_3) + u_t,$$

where $P_{t-1}^e(\beta_3) = \beta_3 \sum_{i=0}^{\infty}(1 - \beta_3)^i P_{t-i-1}$, and

$$V_{t-1}^e(\beta_3) = \beta_3 \sum_{i=0}^{\infty}(1 - \beta_3)^i[P_{t-i-1} - P_{t-i-2}^e(\beta_3)]^2.$$

The variable Y_t above is acreage harvested in year t, P_t is price received for the crop in year t, and $P_t^e(\beta_3)$ and $V_t^e(\beta_3)$ are the mean and variance, respectively, of the subjective distribution of year $t + 1$ prices as perceived in year t. A consistent finite approximation to (5) is defined as

$$(6) \quad Y_t = \beta_0 + \beta_1[P^*_{t-1}(\beta_3) + \hat{P}^{**}_{t-1}(\beta_3)] + \beta_2[V^*_{t-1}(\beta_3) + \hat{V}^{**}_{t-1}(\beta_3)] + \epsilon_t,$$

where $P^*_{t-1}(\beta_3) = \beta_3 \sum_{i=0}^{t-t_0-1}(1 - \beta_3)^i P_{t-i-1}$,

$\hat{P}^{**}_{t-1}(\beta_3)$ is a finite consistent estimator of

$$P^{**}_{t-1}(\beta_3) = \beta_3 \sum_{i=t-t_0}^{\infty}(1 - \beta_3)^i P_{t-i-1},$$

Edmund A. Estes is an assistant professor, Department of Economics and Business, North Carolina State University; Leroy L. Blakeslee and Ron C. Mittelhammer are, respectively, professor and assistant professor, Department of Agricultural Economics, Washington State University.

Scientific Paper No. 5451. Work for this paper was done under Project 0330, College of Agriculture, Washington State University.

Special thanks go to Henri Theil, University of Chicago, for allowing the authors access to materials in his yet unpublished second edition of *Principles of Econometrics*.

$$V^*_{t-1}(\beta_3) = \beta_3 \sum_{i=0}^{t-t_b-1} (1 - \beta_3)^i[P_{t-i-1} - P_{t-i-2}{}^e(\beta_3)]^2,$$

and $\hat{V}^{**}_{t-1}(\beta_3)$ is a finite consistent estimator of

$$V^{**}_{t-1}(\beta_3) = \beta_3 \sum_{i=t+t_b}^{\infty} (1 - \beta_3)^i[P_{t-i-1} - P_{t-i-2}{}^e(\beta_3)]^2.$$

Given β_3, equation (6) in linear in β_0, β_1, and β_2. Additional details are given in Just (1974a,b, 1977) and Estes.

In each of the above examples, the likelihood function can be "concentrated" on $p < m$ parameters. Let β be partitioned as $(\beta'_{m-p}\ \beta'_p)'$, and assume the entries in β have been ordered so that

$$(7)\quad F(X_{1t}, \ldots, X_{tk};\ \beta_{m-p}|\beta_p) = X(\beta_p)\beta_{m-p}.$$

Here, $X(\beta_p)$ denotes the fact that the $n \times (m - p)$ matrix of explanatory variables premultiplying the $(m - p) \times 1$ vector β_{m-p} is a function of the p parameters in the column vector β_p. Then given β_p, the logarithm of the likelihood function can be written as

$$(8)\quad \ln L(\beta_{m-p}, \sigma^2|\beta_p) = -\frac{n}{2}\ln 2\pi - \frac{n}{2}\ln \sigma^2 - \frac{1}{2\sigma^2}(Y - X(\beta_p)\beta_{m-p})'(Y - X(\beta_p)\beta_{m-p}).$$

It is clear that the maximum likelihood estimates (MLE) of β_{m-p} and σ^2, conditional on β_p, are standard linear least squares estimates, namely

$$(9)\quad \hat{\beta}_{m-p}(\beta_p) = [X(\beta_p)'X(\beta_p)]^{-1}X(\beta_p)'Y, \text{ and}$$

$$(10)\quad \hat{\sigma}^2(\beta_p) = \frac{1}{n}[Y - X(\beta_p)\hat{\beta}_{m-p}(\beta_p)]'[Y - X(\beta_p)\hat{\beta}_{m-p}(\beta_p)].$$

Substituting (9) and (10) into (8) yields the concentrated likelihood function, equation (11).

$$(11)\quad \ln L^*(\beta_p) = \max_{\beta_{m-p},\sigma^2} \ln L(\beta_{m-p}, \sigma^2|\beta_p) = -\frac{n}{2}(\ln 2\pi + 1) - \frac{n}{2}\ln \hat{\sigma}^2(\beta_p).$$

The logarithm of the concentrated likelihood function is equal to the logarithm of the original likelihood function partially maximized with respect to β_{m-p} and σ^2. Therefore $\ln L(\beta, \sigma^2)$ can be maximized by choosing the vector, β_p, which minimizes $\hat{\sigma}^2(\beta_p)$. Then the MLE for β_{m-p} is $\hat{\beta}_{m-p}(\tilde{\beta}_p)$, and the MLE for σ^2 is $\hat{\sigma}^2(\tilde{\beta}_p)$.

If p is small, say ≤ 3, and if β_p can be a priori restricted to a small subspace of R^p, then a search algorithm based on linear least squares is suggested by the results (7) through (11). Linear least squares estimates $\hat{\beta}_{m-p}(\beta_p)$ and $\hat{\sigma}^2(\beta_p)$ defined in (9) and (10) are calculated for values of β_p that have been chosen to cover the relevant values with a degree of accuracy chosen by the researcher. That value $\tilde{\beta}_p$ that yields the smallest $\hat{\sigma}^2(\tilde{\beta}_p)$ is the maximum likelihood estimator of β_p in the nonlinear model (1). The $\tilde{\beta}$ vector is composed of $\tilde{\beta}_p$, and the corresponding linear least squares estimate $\hat{\beta}_{m-p}(\tilde{\beta}_p)$ as $\tilde{\beta} = (\hat{\beta}_{m-p}(\tilde{\beta}_p)'|\tilde{\beta}'_p)'$. The values of β_p can be simply specified on a grid, or if β_p contains only a single element, the values may be chosen in a more efficient manner, say through a Fibonacci search. The linear least squares search algorithm above is recommended by Dhrymes in his work on distributed lags, and is the one used by Just (1974a,b) in his empirical work.

The asymptotic covariance matrix for the above parameter estimates may be estimated by the inverse of the information matrix, i.e., $-[E(\partial^2 \ln L/\partial\beta\partial\beta')]^{-1}$, which for models of type (1) can be consistently estimated in the following form:[1]

$$(12)\quad \text{asy}\,\hat{}\,\text{cov}\ \tilde{\beta} = \hat{\sigma}^2\left[\sum_{t=1}^{n}\frac{\partial Y_t}{\partial\beta}\left(\frac{\partial Y_t}{\partial\beta}\right)'\right]^{-1}.$$

Here, the derivatives are evaluated at the M.L. estimated point $\beta = \tilde{\beta}$. For models that are conditionally linear of the type (7), (12) further specializes to

$$(13)\quad \text{asy}\,\hat{}\,\text{cov}\ (\tilde{\beta}) = \hat{\sigma}^2(\beta_p)\left[\begin{array}{c|c} X(\tilde{\beta}_p)'X(\tilde{\beta}_p) & X(\tilde{\beta}_p)'\dfrac{\partial Y}{\partial\beta_p} \\ \hline \left(\dfrac{\partial Y}{\partial\beta_p}\right)'X(\tilde{\beta}_p) & \left(\dfrac{\partial Y}{\partial\beta_p}\right)'\dfrac{\partial Y}{\partial\beta_p}\end{array}\right]^{-1}$$

$$= \hat{\sigma}^2(\tilde{\beta}_p)\left[\begin{array}{c|c} M_1 & M_2 \\ \hline M'_2 & M_3\end{array}\right]^{-1} = \hat{\sigma}^2(\tilde{\beta}_p)\left[\begin{array}{c|c} R_1 & R_2 \\ \hline R'_2 & R_3\end{array}\right]$$

where $\partial Y/\partial\beta_p$ is evaluated at the point $\tilde{\beta}$.

Rather than use the inverse of the information matrix, it is tempting to continue the analogy with linear least squares and consider the estimated covariance matrix routinely produced by least squares procedures once $\tilde{\beta}_p$ has been determined, i.e.,

$$(14)\quad \hat{\text{cov}}\,[\hat{\beta}_{m-p}(\tilde{\beta}_p)] = \hat{\sigma}^2(\tilde{\beta}_p)[X(\tilde{\beta}_p)'X(\tilde{\beta}_p)]^{-1},$$

as a measure of dispersion for the estimates $\hat{\beta}_{m-p}(\tilde{\beta}_p)$. In recent work, Just (1977) indicates that the inverse of the information matrix provides proper estimates of asymptotic variances of estimated coefficients; but in his empirical supply analysis, (14) is used as a measure of asymptotic estimator precision and for hypothesis testing. Unfor-

[1] Results in articles by Just, Wolfowitz, and Jennrich can be used to show that given the i.i.d. normality assumption, maximum likelihood parameters estimates will be consistently and asymptotically normal if the function F is twice differentiable with respect to β in a neighborhood of the true β, and

$$\lim_{n\to\infty}\frac{1}{n}\sum_{t=1}^{n}\left[\frac{\partial Y_t}{\partial\beta}\left(\frac{\partial Y_t}{\partial\beta}\right)'\right] = Q,$$

where Q is symmetric positive definite. The particular form of the information matrix used in (12) is from Theil.

tunately, although (14) can be computed rather effortlessly, and in fact is usually standard output for most linear least squares computer routines, it is incorrect as a measure of the precision of the estimates $\hat{\beta}_{m-p}(\tilde{\beta}_p)$.

Aside from the fact that (14) provides absolutely no information about variances and covariances of entries in the $\tilde{\beta}_p$ vector nor about covariances between $\hat{\beta}_{m-p}(\tilde{\beta}_p)$ and $\tilde{\beta}_p$, what interpretation is to be given to (14)? Certainly, it is a conditional variance-covariance matrix estimate in the sense that its elements can be computed only with β_p given. But it is also conditional in a more fundamental sense. Given the asymptotic normal limiting distribution of $\sqrt{n}(\hat{\beta} - \beta)$, a conditional limiting distribution for $\sqrt{n}(\hat{\beta}_{m-p}(\tilde{\beta}_p) - \beta_{m-p})$ given $\tilde{\beta}_p = \beta_p$ can be derived. The covariance matrix (14), when multiplied by n, is a consistent estimate of the covariance matrix of this conditional limiting distribution. However, (14) multiplied by n does not provide a consistent estimate of the covariance matrix of $\sqrt{n}(\hat{\beta}_{m-p}(\tilde{\beta}_p) - \beta_{m-p})$ in the unconditional limiting distribution, which is clearly the covariance matrix of interest in defining the asymptotic covariance matrix of $\hat{\beta}_{m-p}(\tilde{\beta}_p)$.

The result (13) together with the method of partitioned inversion (Goldberger, pp. 27–28) can be used to show that the conditional asymptotic covariance matrix estimates systematically overstate the precision of the parameter estimates $\hat{\beta}_{m-p}(\tilde{\beta}_p)$. The conditional covariance matrix (14) is representable as $\hat{\sigma}^2(\tilde{\beta}_p)M_1^{-1}$, while by partitioned inversion, the submatrix of (13) corresponding to the unconditional covariance matrix of $\hat{\beta}_{m-p}(\tilde{\beta}_p)$ is

$$(15)\quad \sigma^2(\tilde{\beta}_p)R_1 = \sigma^2(\tilde{\beta}_p)[M_1 - M_2M_3^{-1}M'_2]^{-1}$$
$$= \hat{\sigma}^2(\tilde{\beta}_p)[M_1^{-1} + M_1^{-1}M_2$$
$$(M_3 - M'_2M_1^{-1}M_2)^{-1}M'_2M_1^{-1}].$$

The difference in covariance matrix estimates is then

$$(16)\quad \hat{\sigma}^2(\tilde{\beta}_p)M_1^{-1} - \hat{\sigma}^2(\tilde{\beta}_p)R_1$$
$$= \hat{\sigma}^2(\tilde{\beta}_p)M_1^{-1}M_2(M'_2M_1^{-1}M_2 - M_3)^{-1}M'_2M_1^{-1},$$

which is negative semidefinite because the inverse of the matrix in parentheses equals $-R_3$, where R_3 is a principal submatrix of a positive definite covariance matrix, and hence is itself positive definite. Therefore, PR_3P' is positive semidefinite for any P, and it follows that (16) is negative semidefinite. Since the difference in variance estimates associated with a linear combination of the parameter estimates can be written as $\hat{\sigma}^2(\tilde{\beta}_p)C'[M_1^{-1} - R_1]C$, where C defines the linear combination, and since (16) is negative semidefinite, the variance will in general be understated using the conditional covariance matrix. Furthermore, this difference is accentuated as $\hat{\sigma}^2(\tilde{\beta}_p)$ increases. It is clear from (16) that there will be no understatement of the variance of $C'\hat{\beta}_{m-p}(\tilde{\beta}_p)$ only if $M'_2M_1^{-1}C$ is the zero vector.

Finally, regarding the conditional covariance matrix, Just (1974a) has stated, "Although the standard errors reported . . . are conditional on Θ, they apply unconditionally in an asymptotic sense because Θ and ϕ are estimated consistently. Thus a discussion of the significance of results is possible although somewhat less confidence may be placed in the conclusions" (n. 15, p. 22). In a similar statement elsewhere, Just remarks, in reference to the use of conditional covariance matrices, that "t-ratios can be calculated by the usual procedure in testing and determining the significance of any coefficient estimated . . . although the significance levels indicated by the t-distribution only apply asymptotically" (Just 1974b, suppl. p. 25).

While it is true that the estimated conditional and unconditional standard errors are asymptotically equivalent in the trivial sense that they both approach zero with probability one as $n \to \infty$, this clearly does not establish the large sample validity of (14) for measuring estimator precision or for use in constructing hypothesis tests. The significance levels indicated by the t-distribution generally will be incorrect even asymptotically when using conditional variance estimates. Consider the linear hypothesis $C'\beta_{m-p} = k$, and form the t-statistic using the conditional covariance matrix (14) as

$$(17)\quad t_c = [C'\hat{\beta}_{m-p}(\tilde{\beta}_p) - k]/(\hat{\sigma}^2(\tilde{\beta}_p)C'M_1^{-1}C)^{1/2},$$

and the unconditional covariance matrix [submatrix of (13)] as

$$(18)\quad t_u = [C'\hat{\beta}_{m-p}(\tilde{\beta}_p) - k]/[\hat{\sigma}^2(\tilde{\beta}_p)C'M_1^{-1}C]^{1/2}.$$

By multiplying the numerator and denominator in (17) and (18) by $\sqrt{n}$, and letting $n \to \infty$, it is recognized that under the null hypothesis, H_0, t_u converges in distribution to a standard normal variate, and t_c converges to a random variable distributed as $N(0, \xi)$, where the variance $\xi \geq 1$ with strict equality holding in the limit iff $p\lim \frac{1}{n} C'M_1^{-1}M_2 =$ [0] (see limit theorems in Rao, p. 122). Thus, for any finite critical values $= k$ and under H_0 as $n \to \infty$,

$$(19)\quad \alpha_c = Pr[t_c \notin (-k, k)]$$
$$\geq Pr[t_u \notin (-k, k)] = \alpha_u,$$

where the probabilities α_c and α_u correspond to rejecting the null hypothesis using t_c and t_u, respectively. It is clear that if $k = t_{\alpha/2}$, where $t_{\alpha/2}$ is the critical value of the t distribution with α-level tail probability, then in the limit $\alpha_c \geq \alpha_u = \alpha$, so that a decision rule based on t_c generally accepts the alternative hypothesis too often.

In the next section we present empirical comparisons of variances and significance tests calculated in the two ways above.

Empirical Results

Just's generalized adaptive expectations model was recently applied in estimating potato acreage re-

sponse for six regions of the United States (Estes). Models of the type (6), but generalized to include other conventional regressors and expected substitute prices, were estimated using a conditional linear least squares algorithm. The specific model formulation and estimation procedure is an extension of the one proposed by Just (1977) and is discussed in detail in Estes.

Specifically, an estimation procedure was used in which the likelihood function was concentrated on the coefficient of adjustment [β_3 in model (5)], and a coarse grid search combined with a Fibonacci search was conducted over the (0, 1) interval for β_3. The interval (0, 1) is consistent with Just's (1974a) work, where he assumes that if "the state of the economic environment is positively related to the state of the immediately preceding time period, then the decision makers optimal . . . value would lie in the unit interval" (n. 5, p. 16). Given β_3, the model (6) is conditionally linear in the sense of (7). For each value of the conditioning parameter β_3 considered, a linear regression involving the remaining parameters was calculated and the residual sum of squares associated with the given β_3 value was determined. The maximum likelihood estimates were the value of $\tilde{\beta}_3$ and the values of the remaining parameter estimates, say $\hat{\beta}(\tilde{\beta}_3)$, in the associated linear regression that minimized the sum of squares to a prespecified tolerance.

Variances and covariances of coefficients, as well as asymptotic t-values, were calculated using both the conditional covariance matrix in (14), and the unconditional covariance matrix in (13). Results shown for Maine in table 1 are fairly typical of those found in the six regions in terms of overall goodness of fit.

The R^2 value was .821; all coefficients have the expected signs. As indicated by previous arguments, all t-values are smaller when calculated via the information matrix than when calculated with variances from the conditional distribution. For coefficients of mean and variance of potato price, t-values from the information matrix are less than half the values calculated with conditional variances. In addition, the information matrix approach suggests that the coefficient of adjustment [corresponding to β_3 in (5)] has been estimated fairly reliably, while the conditional variance-covariance matrix provides no information on this point.

Table 1 also provides similar information on the equation having the lowest R^2 of any of the six which were estimated, that for the Red River Valley. Here the R^2 was .545. In this case, t-values generally appeared somewhat marginal when calculated with conditional variances. When calculated via the information matrix, t-values provided little evidence of statistical significance in several cases.

Conclusions

Conditional linear least squares is an appealing estimation technique where it is applicable. However, an extension of these procedures to calculation of standard errors of coefficients often will produce seriously misleading estimates of precision. Further, the errors will all be in one direction, causing researchers to place too much confidence in their results, and rejecting single and joint null hypotheses too often. Where applicable, an alternative procedure based on the information matrix provides estimates of asymp-

Table 1. Estimated Coefficients and Alternative t-Values for Maine and Red River Valley Potato Acreage

Simulated Behavior of Fast Food Restaurants under Alternative Cost/Volume Conditions

Lynn W. Robbins and Thomas P. Haas

The food service industry has become a major factor in total retail food sales during the past decade. Expenditures for food away from home were about 35% of all food expenditures in 1978. Between 1963 and 1978, fast food restaurant sales increased 305%, adjusted for inflation. Fast food restaurants are defined as eating establishments that utilize standard food preparation, service, equipment, management systems, and labor savings technologies in providing a limited food menu. Their share of total eating place sales more than doubled from 1963 to 1972. This share undoubtedly will show further increases as more recent data become available (Van Dress).

Changes in the socioeconomic structure of American society, such as the increasing number of working wives and single person households along with changes in income, tastes, preferences, eating habits, and a general transition to more leisure time, have contributed to expansion in food service. Growth of this magnitude creates informational needs among both industry and public sector participants. Typically, the appearance of economic, marketing, and management information about a new sector of the economy lags its growth in importance. Because of fast food's especially rapid growth, the related informational demand is large. While some research relating to fast food and other food service industries exists, information remains relatively scarce (Haas, p. 89).

A typical fast food restaurant's behavioral and operational relationships are described in detail. Some opportunities for improved marketing and operational efficiency are identified. The typical fast food restaurant is modeled and analyzed using sensitivity analyses. That is, model parameters are systematically altered to evaluate potentially viable operating policies that would be costly, time consuming, and impractical to test in reality.

In a micro sense, efficiency improvements reduce operating costs and in turn increase short-run firm profits. Industry-wide competition is enhanced as information on efficient processing and marketing reaches other firms. If marketing costs are reduced across the entire system, greater returns to producers and lower prices to consumers should result.

Research Design

Primary data were collected from a firm that franchises more than 100 fast food retail units in the southeastern United States. Selected management personnel were interviewed. Several restaurant operations were observed. Financial data were collected from eighteen restaurants stratified by sales volume from the smallest to the largest (table 1). The restaurants prepare and sell hamburgers, fish, chicken, french fried potatoes, and soft drinks, as well as offering breakfasts that include ham and eggs or sweet rolls. Meals can be eaten in the restaurant or packaged for take-out. Like most other fast food restaurants, the cooperating organizations' retail units originally offered only take-out service and later added the "eating-in" capability. Some units also added drive-up service after this study was completed.

Based on a combination of observed and recorded data and statistical results, a simulation model was constructed to mimic fast food restaurant's operating dynamics. Operational costs were tabulated and separated into fixed and variable cost components. Labor cost was determined for typical units of various sizes. Purchase dynamics were simulated using a stochastic sales generation sequence. Other operational dimensions were included in the model where quantitative relationships between dynamic components could be specified. A cumulative annual profit was simulated for the typical retail unit based on a series of daily simulation iterations. The DYNAMO Simulation Language (Pugh) was utilized.

The Simulation Model

Figure 1 provides a schematic representation of a retail fast food restaurant. Symbols are consistent with Forrester's System Dynamics methodology and variable names are defined in table 2. Circled terms are rate equation components. Rate equations are indicated by the valve symbols (fig. 1). System levels or states are enclosed in rectangles. Free-standing, underlined, parameter names indicate constant or coefficient terms. The systems cash flow follows the solid lines connecting symbols, while broken lines indicate information or influence flow between components.

Customer Purchase Component

Customer purchases influence marketing efficiency by generating cash flow. Customer volume is represented by dollar sales generated from a purchase rate. The simulator includes a stochastic element which creates a random customer-count response pattern within predetermined bounds. Customer response modeling is facilitated using a random number generator, NOISE, which produces uniformly distributed random numbers between −0.5 and +0.5. Customer purchase response will therefore be uniformly distributed about the constant multiplier value and constraint at the extreme by expansion or compression of the NOISE bounds. Customer response can be tailored to fit specific existing locations or proposed locations, given specific or expected traffic volume.

Average daily advertising expenditures are added directly to cost components at each time step. Actual purchases comprising cash flow dollars are created using a purchase rate equation. The purchase rate depends upon the average purchase size, which translates physical customer volume into a dollar sales volume according to the relationship:

$PURCH = ADDRAW * APS * DLINF3\ (PMA)$,

where *PURCH* is Purchase rate, *ADDRAW* is Average daily draw (customer count), *APS* is Average purchase size, *DLINF*3 is Information delay, and *PMA* is Purchase multiplier due to advertising. *DLINF*3 is an information delay that corresponds with the tendency for advertising to exhibit a lagged response.

Labor Utilization and Cost Components

Unit labor requirements are, to an extent, fixed by individual unit operational requirements. A basic core of employees is necessary regardless of volume. Personnel are constantly necessary for specific work stations. As volume increases, additional personnel are required to serve overburdened

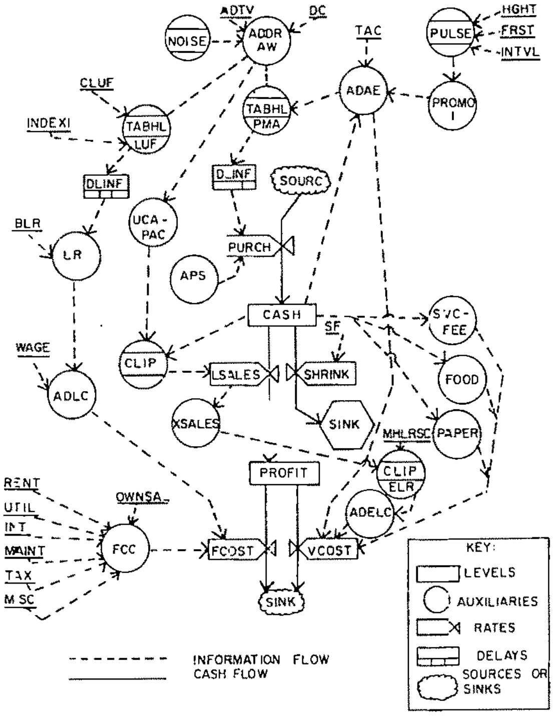

Figure 1. Fast food retail store system simulation flow chart

work stations and provide extra services, cleanup for example. While the division between basic unit requirements and variable needs is somewhat arbitrary, the model computes basic needs according to typical unit labor requirements for the lowest volume stores. The model can mimic decreased labor requirements based on improved labor utilization.

Actual labor requirements are simulated in two separate stages (both dependent upon labor productivity). Basic labor requirements and labor costs are represented by constant relationships. The second simulation stage computes additional labor requirements due to sales beyond those of the base requirements. This total labor cost component is then added to the variable cost rate equation.

Fast food restaurant operations are geared for rapid, high volume service. At some volume level, based on sales and customer count, the retail unit will encounter capacity limitations. When designed store volume is exceeded, normal work flow or service will be hampered and efficiency decreased. Additionally, lost sales may result.

Capacity restrictions are based on information provided by the cooperating firm managers. A rate equation for lost sales reflects the sales-diminishing tendency when capacity is exceeded. This cash flow drain reduces normal profits.

Cost-Profit Components

Cash flow behavior is modeled to follow the pattern existing in a cooperating organization retail store. Cost rate components represent true operational cash flow drains classified according to their fixed and variable sources. A profit-level equation is used to accumulate daily profit and loss through the course of 365 daily time steps. Individual cost sources are altered to allow for analysis of that component's impact on profit.

Rent, utilities, interest on debt, maintenance costs, taxes, and several incidental costs were classified as fixed. These costs vary little with volume changes. These fixed costs are combined with the fixed portion of labor costs necessary for basic unit operations.

Variable cost components consist of the service fee paid to central operations based on unit sales, food input costs, paper cost, average daily advertising expense, and variable labor cost above the basic

MAINT:	Maintenance cost	*XSALES:*	Extra sales

unit operational needs as defined in the labor utilization section. Additional labor costs are computed using an auxiliary which multiplies additional physical labor requirements by a wage rate component.

Actual costs are used in the simulator from the eighteen restaurants. This sample is stratified to include three units from each of six volume categories. Sample stores were drawn at random from the total cooperating organization's retail system until three sample units were attained for each volume stratum. Each volume category contains an equal number of units reflecting an almost uniform distribution of retail units from smallest to largest. Units opened within the year prior to sample selection were excluded because their cost experience is unique during the normal "startup" period. Average costs for each sales volume stratum for all cost components were calculated from actual financial statements. Table 1 lists these averages and a composite average for all stores.

Simulator Validation

The basic model was formulated to depict behavior for a cooperating organization restaurant in the sixth or lowest sales volume stratum (table 1). Results simulate a cumulative $11,518 loss for a typical store in the sixth category. Actual losses for the average stratum 6 store are $9,192. Modeling error, defined as the error in simulating the correct sales figure amounts to less than 1%. Figures for average daily advertising expense, cash flow, fixed and variable costs, and labor cost are typical for stores in this sales stratum. With actual sales exceeding simulated sales by $2,200.00 and expenses simulated accurately; simulated profit necessarily would be $2,200.00 low. Hence, the model is considered to be valid for restaurants franchised by the cooperator and will allow for adequate sensitivity analyses and evaluation.

Sensitivity Analysis Results

Firm cash flow depends in part on the average purchase per consumer. The cooperating restaurants' average purchase size ($1.50) was analyzed by increasing it over the range from $1.50 to $1.70. Simulated responses for the representative sample of purchase sizes are shown in figure 2. Results indicate that profits are sensitive to average purchase size. An increase in purchase size of 20¢ results in more than $13,000 of added returns per year. However, cooperating firm managers estimate that such an increase in average purchase size could not be generated from the estimated added revenue.

The model includes the system's behavioral decision rule that keeps advertising at some relatively constant percentage of sales. Consequently, some added advertising expense was accounted for by

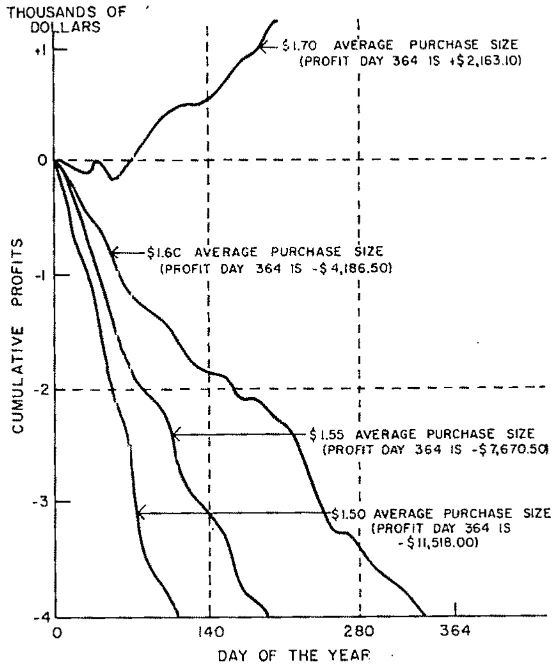

Figure 2. Simulated sensitivity of fast food retail profits to various average purchase sizes for a typical small volume store

the model as average purchase size was increased externally. The managers' assessment of the situation, however, is that a much greater promotional attempt would be needed to achieve an average purchase size of $1.70 than could be generated from the expected additional revenue. Even though profits are sensitive to average purchase size, average purchase size is not sensitive to attempts at increasing it. In essence, profits are insensitive to reasonably expected increases in purchase size.

Figure 3 depicts the results of increasing customer count. Count is at least as, if not more, sensitive than average purchase size. Managers view the likelihood of increasing count to the magnitudes analyzed in figure 3 to be much higher than similar magnitudes for purchase size. Apparently fast food restaurants are the size they are not because of individual purchase sizes but because of customer count. If a restaurant's management cannot increase customer count, continued viability must rely on cost effectiveness not revenue enhancement.

In fast food retailing, labor costs depend heavily upon the minimum wage rate. The basic model used a wage rate very near the current minimum wage rate. A lower minimum wage in the future is highly unlikely, therefore the sensitivity analysis only includes increases in wage rates for the basic store, figure 4, and for a typical high volume store, figure 5. Wage rate increases placed substantial strains on cash flow. For the low volume store, losses in-

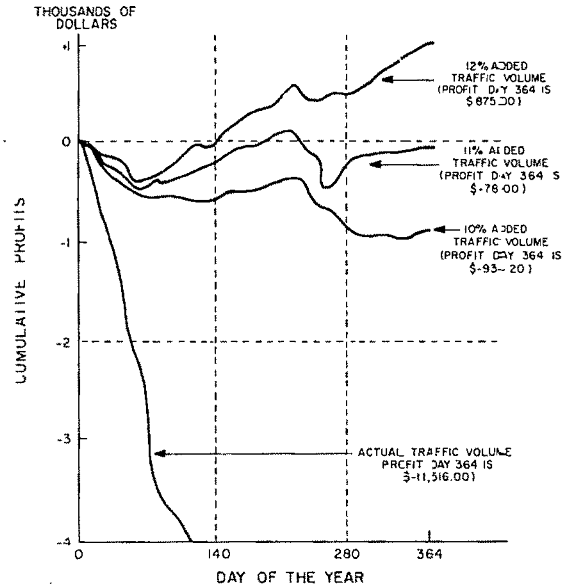

Figure 3. Simulated sensitivity of fast food retail profits to various average traffic volumes for a typical small volume store

creased more than twofold for a 30¢ increase in the average wage. Profits of high volume stores decreased by about one-third for a 30¢ wage increase.

Food and paper costs are specified as a percentage of sales. Sensitivity changes are accomplished by changing the coefficients that determine food and paper costs. Changes were tested against the basic store volume and a typical large volume store with cumulative profits amounting to $48,000. The changes for the typical large volume store are depicted in figure 6.

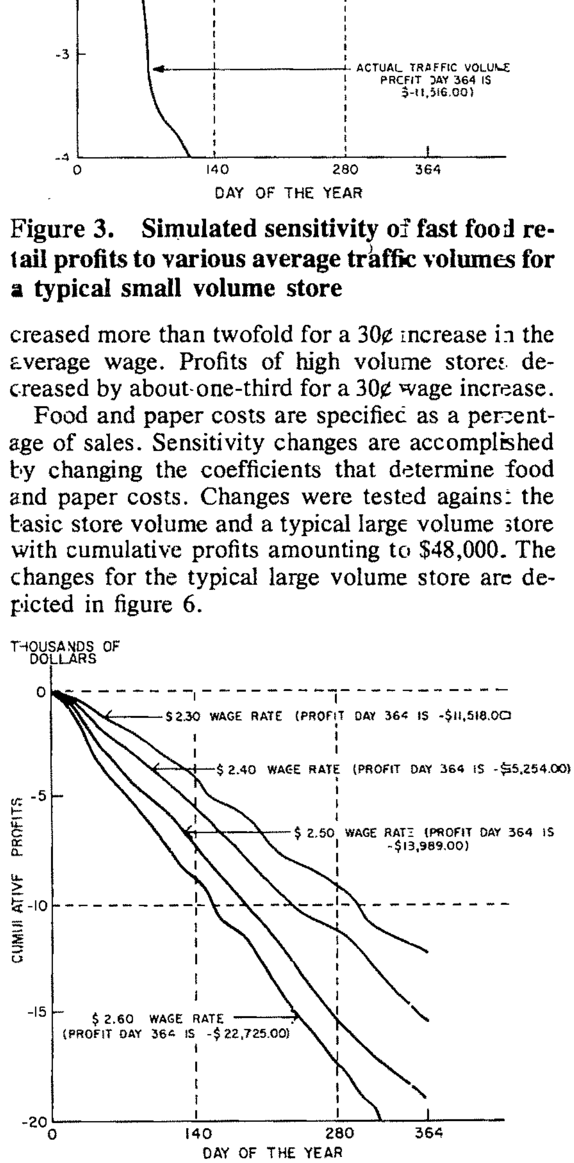

Figure 4. Simulated sensitivity of fast food retail profits to various levels of wage rates for a typical small volume store

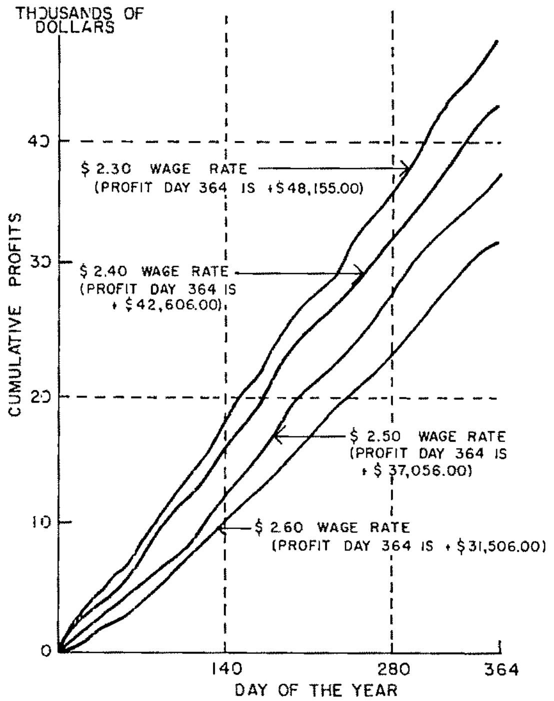

Figure 5. Simulated sensitivity of fast food retail profits to various levels of wage rates for a typical large volume store

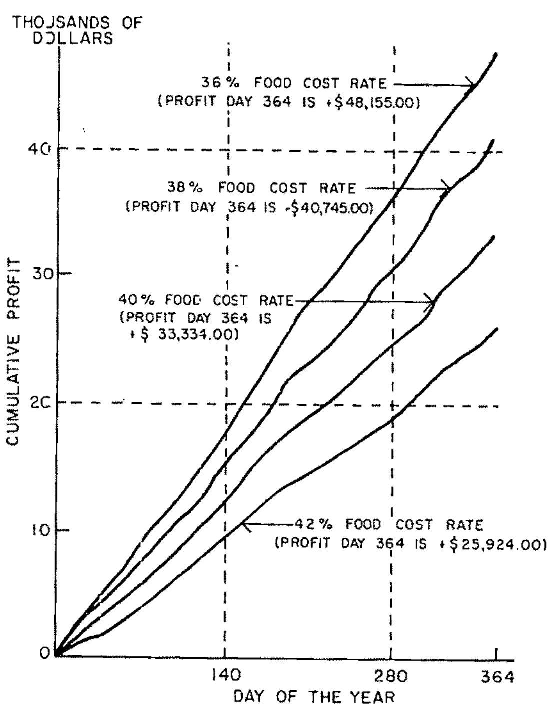

Figure 6. Simulated sensitivity of fast food retail profits to various levels of input costs for a typical large volume store

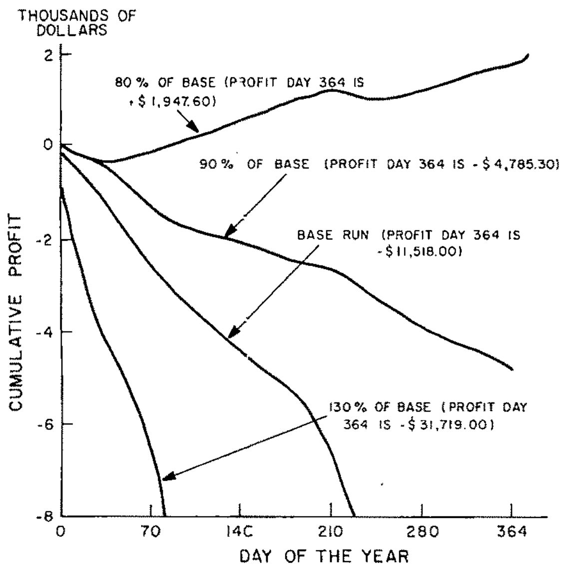

Figure 7. Simulated sensitivity of fast food retail profits to various levels of fixed costs for a typical small volume store

For the small volume unit, food costs totaling 42% of sales, as opposed to 36% in the basic model, almost treble the simulated cumulative loss. In the large volume store's case, an equal percentage food cost increase decreases profits by over 50%.

The fixed-costs variable represents a variety of fixed-cost components. Rather than test each component's sensitivity, the components were treated as a sum and indexed such that selected percentage changes in the total could be tested. In the base model, the index value is 1.0. Fixed-cost indices are tested for values ranging from 0.8, which represents a 20% decrease in all fixed-cost components, up to 1.3, representing a 30% increase in fixed costs. These changes are shown in figure 7. Basic model behavior is sensitive to fixed-cost adjustments.

Conclusions and Implications

This paper assessed particular operational criteria where marketing or operating efficiencies might be captured. Simulation analysis allowed potential operational changes to be tested against retail system behavior.

The DYNAMO-based simulation model mimicked retail operations and was accurate to within 1% of sales. The analysis revealed that many operational aspects, such as labor and food input utilization, contain sensitive parameters. Sensitive retail unit parameters are labor costs, food costs, fixed costs, average purchase size, and average traffic volume.

Four specific simulation-related conclusions and one overall conclusion came out of this research effort. First, successful attempts at increasing average purchase size provide substantially more revenue. Average traffic volume is similarly and possibly even more sensitive. The consensus among cooperating firm managers is, however, that increases in traffic count of the magnitude analyzed would be much more easily attained than those magnitudes analyzed for average purchase size. Consequently, it would appear that promotions intended to increase average purchase size, and only the average purchase size, should be discouraged. The most profit effective promotion apparently should emphasize customer count and not purchase size.

Second, profits are highly sensitive to labor costs. Increased wages decreased profits for all restaurant sizes, but smaller volume stores are more prone to pressures generated by wage increases. Current legislation and pressures from unions and other organizations aimed to increase the minimum wage rate will have a marked effect on fast food profit performance. Because labor cost constitutes a major expense category in fast food restaurants, increased efficiency can lead to significant operational economies.

Caution is required with respect to the partial equilibrium assumptions. They are that changes in wages as well as input and fixed costs affect only the simulated firm. The impact upon a firm's profits of an isolated cost increase is not the same as when it is shared by all competitors (as would necessarily be the case of a change in minimum wage). With an across-the-board cost increase, an across-the-board price increase likely would follow. If one restaurant's costs increase, they are much less likely to raise prices.

Third, it is clear that food cost is an important store performance parameter. Profits are very sensitive to food cost changes, particularly the smaller units. These smaller stores may face inefficiencies in food product buying, information discovery, or lack sufficient sales to warrant volume purchasing.

Fourth, fixed cost's sensitivity and therefore its importance is reinforced. Break-even volumes increase markedly with each increase in the fixed-cost components. As smaller volume stores become uneconomical, barriers to entry increase and competitiveness decreases.

Finally, in general it was found that without compensating unit efficiency changes through operating improvements, marketing improvements, or price increases, unit survival may be jeopardized. These pressures affect small restaurants most directly, as small units do not have the capital and informational support available to their larger counterparts. Industry structure may be adversely affected and competition curtailed if many small restaurants are pressured out of the industry. Efficiency improvements are necessary for small restaurant survival. However, large restaurant efficiency improvements result in gains to the entire industry by lowering unit costs. Under competitive conditions, these

efficiency gains will be passed to consumers through lower prices for goods and services in the food service component of consumer expenditures.

Measuring the Cost of Time in Recreation Demand Analysis: An Application to Sportfishing

Kenneth E. McConnell and Ivar Strand

We reckon hours and minutes to be dollars and cents.
—T. C. Haliburton, *The Clockmaster*

Since the work of Cesario and Knetsch, economists have recognized that the opportunity cost of time plays an important role in determining the demand for outdoor recreation. The opportunities one has for spare time are more significant for consumption of time-intensive outdoor recreation activities than for other commodities, especially nondurables. Bishop and Heberlein illustrate "the overwhelming importance of time costs to final [recreational] values. . . . Total consumer surplus is nearly four times as large . . . [when] time costs are added at half the income rate . . . [as when] time costs were set at zero" (p. 21).

Despite the recognition, economists have neither successfully integrated the costs of time with the methods of recreational demand analysis nor reached a consensus on how it should be measured. Brown, Charbonneau, and Hay state, "Finally, the apparently crucial importance of how opportunity cost of time is handled needs further work. While we are convinced it is an appropriate concept, . . . exactly how it should be included and measured . . . remains to be determined" (p. 24). Several approaches have been taken to include it in the travel cost method. One approach (Brown and Nawas, Gum and Martin) suggests that time in transit be considered as a separate independent variable. Another approach (Bishop and Heberlein; Brown, Charbonneau, Hay; Nicols, Bowes, Dwyer; Cesario and Knetsch) measures the cost of time and adds it to other costs. Several approaches have been suggested to measure time costs. One approach is simply to choose an hourly wage, e.g., $2.00 per hour, or perhaps the minimum wage rate. A more flexible but still ad hoc approach is to use some proportion of the individual's wage rate as the opportunity cost of time (Nichols, Bowes, Dwyer). The proportion is usually taken from independent studies and used to value the travel time. This approach is better than using a constant opportunity cost of time because it allows variation across individuals. It suffers because the choice of the percentage of the wage rate is arbitrary, independent of the sampled population. Cesario has discussed the consequences of ignoring time costs and the differences in values arising from alternative measurement approaches.

In this paper, we argue that the opportunity cost of time is some proportion of the individual's market wage rate or income per hour and that this proportion can be determined from sample data. This method permits the proportion to vary from one study to another, rather than imposing either an arbitrary estimate or one from a sample different from the study's sample.[1]

A Simple Model

The recreationist presumably behaves as if to maximize utility subject to time and budget constraints by choosing trips, denoted r. The original travel cost method (Clawson) used trips per capita (z) as the dependent variable. In this paper, we have chosen to use trips per user (r). But $z = \Pi r$, where Π is the participation rate (proportion of population who participate at least once). Various studies (e.g., Deyak and Smith) have shown that decisions to participate are different from decisions about how frequently to participate. As Brown and Nawas point out, there is loss of information in aggregation. Hence it is more efficient to use r as a dependent variable. However, the method we discuss will work for z or r as the dependent variable.

Let utility be $U(x,r)$, where r is recreation trips and x is a bundle of all other goods. If we introduce a proportionate income tax rate of t, the budget constraint is

The authors appreciate comments from two anonymous reviewers, A. Myrick Freeman, III, Filmore Bender, and Virgil Norton.

[1] The method as described is similar in spirit to a method described in Commons. This paper, brought to our attention by a reviewer of a version of this paper, describes a method of choosing the proportion for a log-linear demand function by a search method.

$$(1) \qquad [F(w) + E](1 - t) = px + cr,$$

where w is the amount of time worked, $F(w)$ is income earned from w units of work, E is fixed income, t is the income tax rate, p is the price of the composite bundle, and c is out-of-pocket costs per recreational trip. Before-tax income is $F(w) + E$. It is the most frequent measure available from surveys. Suppose the time constraint is given by $T = ar + w$, when T is total time available and c is the amount of travel time per recreational trip.[2] The problem is to maximize

$$(2) \quad U(x,r) - \lambda\{px + cr - (1 - t)[F(T - ar) + E]\}.$$

The first-order condition for r is

$$(3) \qquad \partial U/\partial r = \lambda[c + a(1 - t)F'(w)].$$

Assuming that p does not vary across individuals, we get the demand function for recreation.

$$(4) \qquad r = f[c + a(1 - t)F'(w)].$$

Income is given by $F(w) + E$, while the marginal opportunity cost of time is $(1 - t)F'$. Define average income by $v = [F(w) + E]/w$. Sufficient conditions for the cost of time [measured by $(1 - t)F'$] to equal v are (a) The tax rate, t, is zero; (b) marginal earnings are constant: $F'(w) = F(w)/w$; and (c) nonwork income, E, is zero.

From these, it appears likely that the opportunity cost of time is less than average income. If the income figure is family income where other family members earn income and $v \equiv$ family income$/w$, the individual's opportunity cost of time will be overstated. The opportunity cost of time will be understated if an individual gets utility from work or if working today is a form of investment which provides higher income in the future.

Suppose the opportunity cost of time is some constant (k) times the average income. Then the demand function is

$$(5) \qquad r_i = f(c_i + ka_iv_i),$$

where $0 < k < 1$ is usually an arbitrarily chosen number and i is an observation index. Instead of choosing k arbitrarily, we let the sample determine k. With a linear form, we have

$$(6) \quad r_i = \beta_0 + \beta_1(c_i + ka_iv_i) + \beta_3Z_i + \epsilon_i,$$

where Z_i is a vector of exogenous variables including a wealth or income proxy and e_i is an error term with the classical specification. We can rewrite (6) as

$$(7) \quad r_i = \beta_0 + \beta_1c_i + \beta_2a_iv_i + \beta_3Z_i + e_i.$$

[2] We assume that a is travel time per trip. This approach implies that the opportunity cost of time spent on site is zero. While this is standard practice (Brown and Nawas; Shulstad and Stoevener), it is an unresolved but important issue (McConnell). We do not attempt to deal with the issue in this paper.

The estimate of k is $\hat{k} = \hat{\beta}_2/\hat{\beta}_1$, where $\hat{\beta}_i$ are the ordinary least squares (OLS) estimates of the parameters of (7). In the following section we show how this method works on a sample of sportfishermen.

An Application to Sportfishing

To test the approach suggested, we use sample data from a 1978 survey of sportfishermen in the Chesapeake Bay region. The complete specification of the equation is

$$(8) \quad r_i = \beta_0 + \beta_1c_i + \beta_2a_iv_i + \beta_3s_i + \beta_4m_i + e_i,$$

where r is the annual sportfishing trips per angler, c is per trip expenses per person, a is the round trip travel time (computed as round trip distance/45 miles per hour), v is average hourly income (annual family income/2080), s is a site variable equaling 1 for residents of Ocean City, Maryland, and 0 otherwise, and m is the length of the angler's boat.

The expected signs and relationships are $\beta_1 < \beta_2 < 0$, $\beta_3 > 0$, $\beta_4 > 0$. The first two inequalities relate to the negative effect of costs, both trip expenses and travel time, on the trips taken per year. Also, $\beta_1 < \beta_2$ implies that the opportunity cost of travel time is less than average income. The site variable (s) attempts to capture variation due to different characteristics of the sites. Since Ocean City, Maryland, was our only resort area, it was given a value of 1 and the other sites given 0. Boat length (m) represents a previous commitment to sportfishing or a wealth proxy. In either case, it should act to increase annual participation.

Fitting equation (8) on the Maryland-Virginia survey gives us

$$(9) \; r = \underset{(3.89)^*}{9.77} - \underset{(2.00)}{.0206c} - \underset{(2.50)}{.0126av} + \underset{(5.06)}{.019s} + .157m,$$

where $N = 415$, $\bar{R}^2 = .10$, $F(4,411) = 12.8$, and asterisk indicates t-statistics under the null hypothesis of no association. For this equation we have used a subset of observations from the sample.[3] The estimated coefficients agree in sign and magnitude with our prior beliefs. The equation fits reasonably well for cross-sectional observations.

[3] The subset of the sample included anglers who made twenty or fewer trips per season. To test whether the groups were different, a Chow test was used. The test statistic [$F(234,412) = 27.3$] permitted rejection at the 99% confidence level of the null hypothesis that the coefficients of the equation (9) were the same for anglers with twenty or fewer trips and anglers with more than twenty trips. We report results only for the twenty or fewer group. The hourly income variable was based on seven annual income categories ($0–$4,999; $5,000–$9,999; $10,000–$14,999; $15,000–$19,999; $20,000–$29,999; $30,000–$49,000; $50,000 and above) with the average of the category range being assigned to respondents in the category. No respondents from the lowest range were used because respondents not wishing to reveal their income often responded by indicating the lowest income class. This exclusion limits the range of v but appeared more appropriate than introducing considerable error and biased data by inclusion. For a detailed description of the survey, see Strand and Yang.

Using equation (9), we can infer that a representation angler values time at about 60% of his hourly income:

(10) $\hat{k} = \hat{\beta}_2/\hat{\beta}_1 = -.0126/-.0206 = .612.$

We expect that k will vary among regions and sites and that this value is applicable only to our sample. However, by estimating it directly from observations on individual behavior we have eliminated the need for ad hoc and arbitrary valuation of the opportunity costs of time.

Properties of $\hat{k}$

As we have observed, variations in k cause considerable variations in estimates of consumers' surplus. Our value of $\hat{k}$ is not the true value but rather the ratio of two random variables; hence, it is a random variable itself. The reliability of the estimate of consumers' surplus depends on the random properties of $\hat{k}$.

We can ascertain something of the underlying probability distribution of $\hat{k}$ from what we know of $\hat{\beta}_2$ and $\hat{\beta}_1$. Under classical assumptions, the distribution of these coefficients is jointly normal. The distribution of the ratio of two $N(0,1)$ variables is a standard form Cauchy (Johnson and Kotz, chap. 16). However, if the variables forming the ratio are jointly dependent, as are $\hat{\beta}_1$ and $\hat{\beta}_2$, then the underlying distribution is more complex (Springer, chap. 4). In both cases, however, the distributions do not have finite moments. Since confidence intervals and significance tests rely on the existence of second moments, neither of the traditional tests is applicable. We can develop some understanding of the dispersion of $\hat{k}$ by Monte Carlo studies of the ratio of jointly normal variates. This procedure offers guidance about the distribution of $\hat{k}$.

Let the joint density function of $\hat{\beta}_1$ and $\hat{\beta}_2$ be given by $f(\hat{\beta}_1,\hat{\beta}_2)$. Then

(11) $f(\hat{\beta}_1,\hat{\beta}_2) = f_1(\hat{\beta}_1)f_2(\hat{\beta}_2|\hat{\beta}_1),$

where $f_1(\hat{\beta}_1)$ is the marginal density function of $\hat{\beta}_1$, and $f_2(\hat{\beta}_2|\hat{\beta}_1)$ is the conditional density function of $\hat{\beta}_2$ given $\hat{\beta}_1$. With these conditions, it can be shown that

(12) $\hat{\beta}_1 \sim N(\beta_1,\sigma_1^2)$, and

(13) $\hat{\beta}_2|\hat{\beta}_1 \sim N[\beta_2 + \rho\sigma_2(\hat{\beta}_1 - \beta_1)\sigma_1^{-1},\sigma_2^2(1 - \rho^2)],$

where ρ is the correlation coefficient of the bivariate normal. With conditions (12) and (13) we can construct two random variables which follow (11) by calculating

(14) $\tilde{\beta}_1 = \beta_1 + \sigma_1\Theta_1,$

(15) $\tilde{\beta}_2 = \beta_2 + \sigma_2[\Theta_2(1 - \rho^2)^{\frac{1}{2}} + \Theta_1\rho]$, and

(16) $\tilde{k} = \tilde{\beta}_2/\tilde{\beta}_1,$

where Θ_i are $N(0,1)$ and independent. We performed experiments by drawing sequential pairs of unit normal random variables, assuming that the true value of β_1, β_2, σ_1, σ_2 and ρ were as estimated in equation (9). The assumed values are $-.0206$, $-.0126$, .0067, .0050, and $-.3781$, respectively.

Several experiments with sample size varying from 50 to 1,000 were conducted (table 1). Each row gives the mean value of $\tilde{k}$, the bias $(\hat{k} - \tilde{k})$, $\hat{k}$ being the ratio of estimated coefficients, the proportion of estimates greater than zero, and the proportion of estimates in the unit interval. Based on all experiments, there is an estimated probability of .016 that the estimates of $\tilde{k}$ will be less than zero. Our experiments also show that 66.7% of the sample ratios fell in the unit interval.

Although these results do not have the theoretical support of formal confidence intervals, they are informative. Despite the possibility of substantial dispersion as $\hat{\beta}_1$ approaches zero, the experiments show remarkable conformity with the distribution of estimates. Though we cannot say $\tilde{k}$ is significantly different from zero at the 98.4% level of confidence, it seems reasonable to reject the hypothesis that the ratio is less than or equal to zero.

The alternative to the Monte-Carlo approach is to assume that $\hat{k}$ is asymptotically normal with expected value $E\hat{\beta}_2/E\hat{\beta}_1$ and variance approximated by

$$(17) \quad V(\hat{k}) = (\hat{\beta}_2/\hat{\beta}_1)^2[\hat{\sigma}_1^2/\hat{\beta}_1^2 + \hat{\sigma}_2^2/\hat{\beta}_2^2 - 2\,\mathrm{cov}(\hat{\beta}_1,\hat{\beta}_2)/\hat{\beta}_1\hat{\beta}_2].$$

Using the values of their variables following equation (16), we compute $V(\hat{k}) = .142$. With these assumptions and numbers, we can construct the standard rejection region for the null hypothesis that $k = 0$. For a type 1 error of 10%, the critical region for rejection of the null hypothesis lies beyond .483. Thus, based on this approximation, we would reject the null hypothesis that $k = 0$ because the estimated value of k is .612.

The comparison of the assumption of normality with the Monte-Carlo results indicates the kinds of errors we make by assuming normality. Under the condition that $\hat{k}$ is $N(.612, .142)$, about 80% of observations so distributed will fall in the unit interval, compared with about 67% from the Monte-Carlo results. Thus, this assumption of normality with mean .61 and variance given by (17) leads to underestimating the type 1 error. This difference suggests care in the interpretation of results.

Table 1. Some Properties of $\hat{k}$ from Sampling Experiments

Sample Size	Mean Value	Bias of $\hat{k}$	Relative Frequency $\hat{k} \geq 0$	Relative Frequency $0 \leq \hat{k} \leq 1$
50	.765	$-.154$	.984	.672
500	.886	$-.247$	.983	.662
1,000	.763	$-.152$	.985	.667

Conclusions

This paper offers a method of estimating the opportunity cost of time in the demand for recreation. It can be used simultaneously with travel cost analysis, requiring only the interviewee's wage rate or income as additional data. It eliminates the need to rely on an exogenous estimate of the opportunity cost of time.

We have applied this technique to linear demand curves, and with linear functions, OLS provides direct estimates of the proportion. The general approach of letting the sample data choose the proportion is applicable to any functional form via the use of maximum likelihood techniques. An advantage of estimating k directly by maximum likelihood methods is that its asymptotic properties are well known.

The opportunity cost of time is determined by an exceedingly complex array of institutional, social, and economic relationships, and yet its value is crucial in the choice of the types and quantities of recreational experiences. Because of its complexity, one must be cautious in explaining it simply, as we have. In particular, while this method has promise, the measurements are not inconsistent with several competing hypotheses. For example, income per hour as time cost may reflect a negative income effect for sportfishing or the effect of income on the willingness to pay to avoid travel. In addition, this simple approach cannot explain why the opportunity cost of time is related to income for individuals working fixed hours.

Although this paper suggests a new direction, there are undoubtedly more advances to be made. For example, this method requires that the ratio of the opportunity cost of time to income per unit of time be constant for all sample observations. A significant improvement would be to let this ratio change as a function of leisure time or occupation.

Producer Welfare and the Preference for Price Stability

Andrew Schmitz, Haim Shalit, and Stephen J. Turnovsky

The last few years have witnessed a phenomenal increase in price instability for final goods produced and consumed as well as inputs into production processes. As a result, an extensive literature has developed analyzing the welfare consequences of price stabilization brought about by buffer stock activities. This discussion has focused on the distribution of gains between producers and consumers as well as on the overall benefits to the economy. (For a recent survey of this literature, see Turnovsky 1978.) Much of the theoretical basis for the empirical work on the effects of stabilization policies appeared in the seminal papers by Waugh and Oi. Waugh examined the welfare effects of price instability on consumers while Oi addressed the issue of whether or not producers prefer price instability. For policy makers, the conclusion reached by Oi that producers prefer price instability to stability is somewhat disturbing because most policies—especially those in agriculture—have been aimed at creating price stability.

Recently, Tisdell (1978) extended Oi's analysis in two directions. First, he has shown that precisely the same conclusions hold with respect to instability in input prices. Moreover, under the same conditions to those assumed by Oi for the single-product case, commodity price instability (either in outputs or inputs) raises the expected profit of a multicommodity firm. Thus, the thrust of these contributions is to suggest that, insofar as producers are concerned with expected profit, they will prefer price instability—a result which greatly weakens the argument that producers should support price stabilization policies or any form of marketing arrangement where "pooled pricing" is used.

The purpose of this paper is to generalize the conditions under which producers prefer price stability. A single-product firm is first considered, and results are obtained, opposite to those of Oi, which show that a producer may prefer stability to price instability. Furthermore, this paper explores the welfare implications of price instability for a multiproduct firm, to determine whether or not a theoretical argument can be made that a firm engaged in the production of more than one type of commodity may prefer price stability for some of the commodities it produces but not for the entire set. Unlike in the Tisdell results, the findings in this paper show that a firm may prefer price stability in some products but not in others.

The firm is assumed to maximize its expected utility from profits rather than simply expected profits. The motivation for this assumption is rooted in the fact that every firm faces the possible hazard of a decline in profits that can lead to bankruptcy. Thus, instead of using the criterion of maximum expected present value of profits, over a finite or infinite planning horizon, one could provide a static approximation in the form of maximum expected utility. Then, the concept of risk aversion in the static expected utility maximization model emanates from recognition of the costs of profit variability due to price instability in the dynamic expected profit maximization model.[1] Furthermore, if the decision maker is subjectively risk-averse because of future variable profits, the utility maximization criterion is more than justified. Indeed, it is often argued in the practical stabilization literature that such producers are more concerned with the stability of their earnings than with the expected level, reflecting an attitude of risk aversion. In this case, the expected profit criterion which, in effect, assumes risk neutrality will be an inadequate measure of welfare. Accordingly, the purpose of the present paper is to reassess the benefits to producers from price stabilization in terms of a more general utility function of profits, a procedure used previously by authors in other related contexts (Sandmo, Leland). In doing so, the Oi analysis is generalized with respect to the single product and multiproduct firm.

Single-Product Case

Consider a firm that maximizes its expected utility from profits $E[U(\pi)]$. U is a Von Neumann-Morgenstern utility function assumed to be twice differentiable. It is assumed $U'(\pi) > 0$, reflecting the positive marginal utility of profit, while $U''(\pi) \gtreqless 0$, depending upon whether the firm is risk-averse or risk-preferring. (Throughout this paper, the convention of denoting partial derivatives by appropriate subscripts and letting primes denote total derivatives shall be followed.) The profit π is derived from the production process,

[1] We are grateful to a referee for suggesting this interpretation.

(1) $y = f(\mathbf{x}_1, \ldots, \mathbf{x}_n) \quad f_i > 0, f_{ii} < 0,$

where $i = 1, \ldots, n$, f is a concave production function, $\mathbf{x} = \mathbf{x}_1, \ldots, \mathbf{x}_n$ is a vector of inputs, and y is the (single) output. The firm operates in a competitive environment and cannot influence the price of output or the price of inputs.[2] The prices of inputs are denoted by $w = (w_1, \ldots, w_n)$, while the price of output is p. These are assumed to be random variables with known probability distributions having means $E(w_i) = \bar{w}_i$, $E(p) = \bar{p}$, and a finite variance-covariance matrix. We assume, as did Oi, that the firm's decisions are always executed *ex post*, implying that, once the prices are known, the firm can adjust its inputs so as to maximize its profit. Thus, the firm more properly can be described as operating in a world of price variability rather than price uncertainty as assumed by Tisdell (1963), Sandmo, Leland, and Turnovsky (1973), among others. But the present assumption here is the one generally adopted throughout the stabilization literature. The question to be considered is whether or not the firm prefers unstable prices to prices stabilized at their arithmetic means. In this section, it will be assumed that only one price at a time is variable.

To answer the question, the firm's optimization problem must be considered, which is to

$$\max U(\pi)$$
$$\text{(2)} \qquad \text{subject to } \pi = pf(\mathbf{x}) - \sum_{i=1}^{n} w_i \mathbf{x}_i.$$

The first-order conditions for a maximum are

$$\text{(3)} \qquad pf_i(\mathbf{x}) - w_i = 0,$$

where $i = 1, \ldots, n$, where the second-order conditions are that the matrix $F = (f_{ij})$ be negative definite and are automatically satisfied by the assumption of concavity of f.

Solving (3), the optimal values of inputs and associated output are

$$\text{(4)} \qquad \begin{aligned} \mathbf{x}_i &= \phi^i(p, w_1, \ldots, w_n) \\ y &= \psi(p, w_1, \ldots, w_n), \end{aligned}$$

where $i = 1, \ldots, n$. Substituting (4) into π, the firm's utility resulting from its optimal decisions are

$$\text{(5)} \qquad \begin{aligned} U[\pi] &= U\left[p\psi(p, w_1, \ldots, w_n) - \sum_{i=1}^{n} w_i\phi^i(p, w_1, \ldots, w_n)\right] \\ &\equiv V(p, w_1, \ldots, w_n). \end{aligned}$$

The function $V(p, w) = V(p, w_1, \ldots, w_n)$, which expresses the producer's utility in terms of the prevailing output and input prices, provides the basis for analyzing the benefits from stabilization.[3] Specifically, Jensen's inequality will be used, which asserts that $EV(p, w) \gtrless V(\bar{p}, \bar{w})$, as V is convex or concave in the relevant prices. That is, the producer's welfare will be determined from the price stabilization program in terms of the convexity/concavity properties of $V(p, w)$.

Suppose that the only variable price is p, with factor prices being nonstochastic and remaining fixed at their arithmetic means. According to Jensen's inequality, the firm will lose (gain) from having p stabilized at its arithmetic mean as $\partial^2 V/\partial p^2 >$ $(<)$ 0. The second derivative of (5) with respect to p, taking into consideration that $\mathbf{x}_i$ is implicitly a function of p through (4), yields

$$\text{(6)} \qquad \frac{\partial^2 V}{\partial p^2} = U' \frac{\partial y}{\partial p} + U''y^2.$$

With some manipulation, (7) can be rewritten to give the criterion

$$\text{sgn}\left(\frac{\partial^2 V}{\partial p^2}\right) = \text{sgn}\left[\left(\frac{\mu}{1 + \mu}\right)\epsilon - r\right],$$

where $\epsilon = \frac{\partial y}{\partial p}\frac{p}{y}$, price elasticity of supply, which by virtue of (4) is positive; $r = \frac{-\pi U''}{U'}$, Arrow-Pratt measure of relative risk aversion (see Arrow and Pratt); and $\mu = (py - \sum_i w_i\mathbf{x}_i)/\sum_i w_i\mathbf{x}_i$, profit margin, as measured by profit to cost ratio. Thus, in general, whether or not producers prefer price instability depends upon three parameters: (a) the price elasticity of supply, (b) the profit margin μ, and (c) the coefficient of relative risk aversion r.

If firms are risk-neutral, the criterion (7), and also (6), depend solely on the slope of the supply curve; and as long as this is positive, it will ensure that firms prefer price instability. This, of course, was the basis of the Oi results which will continue to hold if firms are risk takers ($r < 0$). However, if firms are risk-averse, their preference for instability may cease to apply. Indeed, as the degree of relative risk aversion increases, so does the firm's preference for stability over instability. On the other hand, the firm's preference for instability increases with both the profit margin μ and the supply elasticity ϵ. For plausible parameter values, (7) could in fact be of either sign. For example, if the firm's utility function is logarithmic so that $r = 1$ and the profit margin is, say, 20%, so that $\mu = 0.2$, the preference for risk will apply if and only if the elasticity of supply $\epsilon > 6$.

[2] By treating prices as exogenous, this analysis (like the Oi analysis) is only a partial equilibrium one. A complete general equilibrium analysis would require us to endogenize prices, explaining their random movements in terms of stochastic shifts in production and preferences. This analysis does not address itself to the welfare implications for consumers.

[3] The function V is the analogue to the consumer's "indirect utility function," which has proven to be useful in analyzing similar problems for consumers; see, for example, Turnovsky, Shalit, and Schmitz.

Multiproduct Firm

Consider now a multiproduct, multi-input firm as developed within a deterministic context by Pfouts and Henderson and Quandt. The firm now produces m outputs, the prices of which $p = p_1, \ldots, p_m$ are random and uses n inputs, the prices of which $w = w_1, \ldots, w_n$ are also random. As in the single output case, all of these prices are assumed to be known prior to production decisions.

The production process of the firm producing m outputs from n inputs is characterized by the transformation function,

$$(8) \qquad H(y_1, \ldots, y_m, x_1, \ldots, x_n) = 0,$$

where H is assumed to be twice differentiable. It is assumed that H is written in such a way that the partial derivatives with respect to outputs y_j are normally positive, while those for inputs x_i are normally negative.

Thus, the firm's objective is now to max $u(\pi)$. where

$$(9) \qquad \pi = \sum_{j=1}^{m} p_j y_j - \sum_{i=1}^{n} w_i x_i,$$

subject to the production transformation process as expressed by (8). Constructing the Lagrangean expression

$$(10) \quad L \equiv U\left[\sum_{j=1}^{m} p_j y_j - \sum_{i=1}^{n} w_i x_i\right] + \lambda H(y_1, \ldots, y_m, x_1, \ldots, x_n),$$

the first-order conditions for a maximum are

$$(11a) \qquad U'(\pi)p_j + \lambda \frac{\partial H(\cdot)}{\partial y_j} = 0,$$

where $j = 1, \ldots, m$,

$$(11b) \qquad -U'(\pi)w_i + \lambda \frac{\partial H}{\partial x_i} = 0,$$

where $i = 1, \ldots, n$, together with (8) above, where λ denotes the Lagrange multiplier.

The second-order conditions require that the principal minors of the bordered Hessian matrix alternate in sign.

Solving the first-order conditions, the following solutions for the optimal inputs and outputs are obtained:

$$(12) \qquad \begin{aligned} x_i &= \phi^i(p, w) \\ y_j &= \psi^j(p, w) \end{aligned}$$

where $i = 1, \ldots, n, j = 1, \ldots, m$. Substituting (12) into π and into the firm's utility function, we derive the multiproduct analogue of (5), namely,

$$(13) \quad U[\pi] = U\left[\sum_{j=1}^{m} p_j \psi^j(p, w) - \sum_{i=1}^{n} w_i \phi^i(p, w)\right] \equiv V(p_1, \ldots, p_m, w_1, \ldots, w_n).$$

Expression (13) provides the basis for evaluating the desirability of price stabilization for a multiproduct firm.

For expositional ease, consider the important case where only one of the commodity prices is stabilized. Whether or not producers benefit from having the price p_j stabilized at its mean depends upon the convexity/concavity properties of V in terms of p_j. Following the same procedure used in the case of a single-output firm, it can be seen that

$$(14) \quad \operatorname{sgn}\left[\frac{\partial^2 V}{\partial p_j^2}\right] = \operatorname{sgn}\left[\left(\frac{\mu}{1+\mu}\right)\frac{\epsilon_j}{\alpha_j} - r\right],$$

where $\epsilon_j = \frac{\partial y_j}{\partial p_j}\frac{p_j}{y_j}$, elasticity of supply of good with respect to its own price, $\alpha_j = p_j y_j \Big/ \sum_{j=1}^{m} p_j y_j$, share of total revenue contributed by good j, and μ measures the profit margin, as defined above.

The comments made previously with respect to ϵ_j, μ, and r in connection with the single-product firm continue to apply. The interesting difference to note is that now, whether or not a firm prefers price instability with respect to a single commodity of the many it produces depends, in addition, upon the share of the total revenue contributed by this commodity. Thus, the rather strong conclusion can be drawn that a risk-averse firm may prefer instability in some of the markets for its products and not in others. However, as (14) shows, the firm is more likely to prefer price instability in those products that contribute a relatively small proportion to its total revenue.

To give the above result some real-world significance, consider the Australian and Canadian case of marketing wheat. In both countries, marketing boards are the sole sellers of wheat abroad, and the prices received by producers for a given crop year are pooled, such that each producer receives the same price regardless of when during the year the product is sold. (Interestingly, such a system also has been suggested for the United States.) However, in Canada, for crops such as flax and rapeseed, prices fluctuate on a daily basis because these are sold through the Winnipeg Commodity Exchange and not through the Board. Thus, for those crops, the timing of sales is crucial for producers. While producers generally support the Canadian Wheat Board in the marketing of wheat, recently a vote was taken among grain producers to determine if they also wanted a similar marketing system for other crops. The answer was no, and they argued that price stability through pooling was already created for the major crop, wheat, and that they wanted instability in nonmajor crops.

Conclusions

The results of this paper show that, for a multiproduct firm, stability may be preferred for some of

the products produced but not for others. Also, for a single-product firm, price stability may be preferred to price instability. These results, given the assumptions on which they are based, lend at least some support to price stabilization policies. It was shown by Massell and Samuelson that society cannot be made better off by manufacturing price instability once both consumers and producers are taken into account. The results in this paper suggest that stability may be preferable even without considering explicitly the consuming sector.

Supply Response and the Dispersion of Price Expectations

Rulon D. Pope

One of the fundamental problems facing much economic analysis is the implication of aggregation when doing market studies. The conditions for exact aggregation under a variety of definitions and settings have been studied (Paris and Rausser, Theil). The focus of this paper is on supply response in agriculture. Several authors have studied the effects of, and tests for, differential supply response coefficients across individuals or areas when aggregating firms (e.g., Theil, p. 567). Here, these coefficients are assumed to be identical for every firm but another problem is examined when uncertainty is present.

It is well documented that farmers have diverse price expectations (e.g., Bessler). The question occurs as to the effects of such different expectations on aggregate supply response. It is found that the curvature of the supply function is a crucial component of the analysis. For example, if the supply function is strictly concave, an increase in the dispersion of expectations will reduce supply in aggregate.

The Aggregation Formulation

In order to deal with the aggregation question, consider initially N individuals with supply functions,

$$A^i = F(\bar{P}^i) \quad i = 1 \ldots N, \tag{1}$$

where A^i is acreage of the crop supplied by individual i, $\bar{P}^i$ is the expectation of price (or relative price) for firm i.[1] The total market response is

$$A = \sum_i A^i = \sum_i f(\bar{P}^i). \tag{2}$$

Equation (2) can be rewritten, letting N^s be the number of individuals with price expectation, $\bar{P}^s$:

$$A = \sum_{s=1}^{S} N^s f(\bar{P}^s). \tag{3}$$

It is convenient to rewrite (3) by defining $g(\bar{P}^s)$, which maps $\bar{P}^s$ into N^s or gives the number of individuals with expectation, $\bar{P}^s$. Implicitly, it must be assumed that $\sum_s N^s$ and (3) are finite. Let $\Omega = a, b$ denote the range that $\bar{P}^s$ can take; that is, a is the lowest and b is the highest expected price.

Assuming a large number of individuals and boundedness, equation (3) can be written

$$\bar{A} = \int_a^b g(\bar{P}) f(\bar{P})\, d\bar{P}, \tag{4}$$

where $g(\bar{P})$ is assumed for convenience to be continuously differentiable. Equation (4) can be further simplified by assuming that ${}_\Omega\int g(\bar{P})\, d\bar{P}$ is finite (and without loss of generality) and equal to one.[2] Thus, $\bar{A}$ is formed by constructing a weighted average in the discrete case, g resembles a probability density function, and $\bar{A}$ resembles an expectation for the continuous case.

The Implications of Diverse Expectations

Given the above formulation, consider the effects of diverse expectations (i.e., $g(\bar{P})$ is nondegenerate). By Jensen's inequality (Rao)

$${}_\Omega\int g(\bar{P}) f(\bar{P})\, d\bar{P} \lesseqgtr f[{}_\Omega\int \bar{P}\, g(\bar{P})] d\bar{P} \equiv f(P^*),$$

as $f'' \lesseqgtr 0$. That is, for concave f in $\bar{P}$, $\bar{A}$ is less than it would be if all individuals had price expectation, P^*, which is the average of all individuals. The converse holds for convex f and no effect is obtained for disperse expectations in the linear case. Therefore, the effects of diverse price expectations (compared to the case where all expectations are equal to the average) is to reduce (increase) total supply if the supply function is strictly concave (convex) in expected price. When the supply function is linear, diverse expectations have no impact. An attempt by government to stabilize price, and presumably expectations, at the average expected price will increase aggregate supply if the response function of each individual is concave. Such response has nothing to do with risk aversion since presumably each firm is risk neutral as only expected price enters (1)–(4). It is also apparent that any wave of optimism which redistributes the expectations upward from

---

Rulon Pope is an associate professor of agricultural economics, Texas A&M University.

[1] Here, acreage is used as a supply variable. One also could use production when it is nonrandom. When production is random, then expected net revenue per acre may be used in place of expected price with acreage as the decision variable. Clearly, (1) as written holds other economic variables (e.g., input prices) fixed.

[2] Since ${}_\Omega\int g(\bar{P}) d\bar{P}$ is finite, one can always define prices such that the above integral is unity. Though g is written as continuous, a Lebesque-Stieltjes integral may be used for both the discrete and continuous cases. For the purposes here, little generality seems to be lost by assuming a limiting number (∞) N^s continuously on Ω.

point a will increase supply. For example, supply increases are predicted when there is a rumor that the support price for grains will be increased even though the new expected support price is lower than P^*. This is because at least some persons with low expected prices raise their expectations. This is apparent from (4), since $f' = df/d\bar{P} > 0$.

Consider next the marginal impact of a mean-preserving increase in the spread of expectations. Define $\bar{P}^0 = \gamma\bar{P} + \mu$ for all $\bar{P}$. The average price P^* will be preserved as γ increases if $P^*d\gamma + d\mu = 0$ or $d\mu/d\gamma = -P^*$. Note that

$$(4') \quad A(\bar{P}^0) = \int f(\bar{P}^0)\, g(\bar{P}^0)\, d\bar{P}^0$$
$$= \int f(\bar{P}^0) \left(\frac{1}{\gamma}\right) g(\bar{P})\, (\gamma d\bar{P}),$$

where the last equality is obtained through transformation of variables and noting that $d\bar{P}^0 = \gamma d\bar{P}$ with γ and μ fixed. Therefore, differentiating (4′) with respect to γ and evaluating at the original distribution gives the response of an average-preserving spread of the distribution of $\bar{P}$ (see Sandmo for a similar procedure in an entirely different context),

$$(5) \qquad \frac{\partial \bar{A}}{\partial \gamma} = {}_a\!\int f'(\bar{P})\, (\bar{P} - P^*)\, g(\bar{P})\, d\bar{P}.$$

It is not immediately clear from (5) whether the marginal response is negative or positive. However, integration of (5) by parts yields

$$(6) \quad \frac{\partial \bar{A}}{\partial \gamma} = \left[f'(\bar{P}) \int_a^{\bar{P}} (t - P^*)\, g(t)\, dt \right]\Bigg|_a^b$$
$$- {}_a\!\int f''(\bar{P}) \int_a^{\bar{P}} (t - P^*)\, g(t)\, dt.$$
$$= f'(b)\, {}_a\!\int (\bar{P} - P^*)\, g(\bar{P}) d\bar{P} - f'(a) \cdot 0$$
$$- {}_a\!\int f''(\bar{P}) \int_a^{\bar{P}} \bar{P}(t - P^*)\, g(t)\, dt$$
$$= - {}_a\!\int f''(\bar{P}) \left[\int_a^{\bar{P}} (t - P^*)\, g(t)\, dt \right] d\bar{P},$$

where the third equality follows by noting that ${}_a\!\int (\bar{P} - P^*)\, g(\bar{P})\, d\bar{P} = 0$. The square bracketed term in this equation is nonpositive since $P^* = {}_a\!\int t\, g(t)\, dt$. Thus, sign $f''(\bar{P})$ and concavity in $\bar{P}$ implies that a marginal increase in the dispersion of price expectations reduces supply. It is also clear from (6) that larger values of $[f''(\bar{P})]$ imply larger values of $\partial\bar{A}/\partial\gamma$. Thus under concavity, when supply is sharply curved, a larger reduction in supply will occur as individuals' beliefs become more disperse compared to the case where supply is nearly linear.

These analytical results suggest a series of testable hypotheses about the supply effects of the distribution of expectations and its changes over time. However, data on the distribution of expectations and its changes are rare or nonexistent in agriculture. Yet there is little hope of substantiating this particular hypothesis without more data.

If one considers a Bayesian process where prior beliefs are revised by sampling current year's price, then identical priors lead to identical posterior-expected prices (see Theil, p. 666). Thus, the dispersion in expected prices is zero. However, if events turn out such that each person has the same prior mean but different precisions of his expectations, then the posterior-expected prices are not identical. Presumably, the posterior distribution of the current year is modified by other information (e.g., policy announcements) to form the prior for next year's expected price.

An important lesson is suggested by this example. We expect information to be gathered only when we are unsure of the probability distribution. For instance, no experimentation would be undertaken to learn the probabilities associated with the toss of fair coin. Thus, where there is an active information market, this is likely evidence of disperse expectations and differential information. Such information may be especially sought after during periods of increased volatility. The essential point is that we know little about how priors are formed and the nature of the information processed. Thus we can only speculate on the nature of the distribution of expectations across individuals and how it changes. Yet, a priori it does seem likely that an increase in perceived variability in the market leads to greater dispersion in expectations across individuals, and, for a single individual, less precision in his estimates of expected price. (Perhaps one would not expect increased dispersion if futures' prices were used to form producer expectations. However, the Bessler study suggests substantial dispersion of expectations). Thus, one may observe supply response due to increased variability of prices but with all firms risk neutral. The practical implication here is that increases in information or extension work aimed at better informing the "optimists" and "pessimists" (the extremes) may increase (or decrease) supply. Such information need only be directed at the first subjective moment of price, its expectation. That is, if an increased variance of P were to reduce acreage, one need not interpret this as evidence of risk aversion. As shown earlier, if increased variability of price (measured in aggregate, e.g., a distributed lag on historical prices) implies greater dispersion of expected price across individuals, then aggregate supply may respond to the variability of historical prices—even given risk neutrality. This effect occurs because some individuals' expected prices are altered as the environment gets more risky. Yet, each firm in our model is risk neutral and does not respond to subjective variance.

Suppose expected price is perceived by two individuals to be \$3.50 per bushel. Each supply curve is

supply is $\bar{A} = 2 \times 75 \times (3.50)^{.6} = 318$. Consider now the case where the first farmer expects price to be \$4; the other expects \$3. In this case, total supply is approximately 317. Thus, an increase in dispersion in price expectations leads to a reduction in supply. This occurs because when the function is concave, then the decrease in supply by the second farmer outweighs that increase in supply by the first farmer.

The above example can be graphed simply by putting the expected prices in frequency form. This will halve aggregate supply or normalize it on the number of economic agents used in calculating frequencies. We obtain in the first case a frequency of 1 for $\bar{P}$ = \$3.50. In figure 1, aggregate supply is given at $\bar{A}'$(159). In the second case, the frequencies are ½ for \$4 and \$3, respectively. All possible frequencies of \$4 and \$3 and aggregate supply are given by the line aDB. For frequencies of ½, supply is $\bar{A}''$ (158.5) and the distance DC ($\bar{A}' - \bar{A}''$) measures the reduction in aggregate supply due to disperse expectations.

Finally, since the results here depend a great deal on the curvature of the supply function, a few comments are in order on that function's shape. The linear function is not necessarily consistent with theory (Pope). Yet, it may reasonably be considered as a first-order approximation of any arbitrary function. If the supply curve were linear, an increase in the dispersion of expected price (preserving the average) would not change supply. Yet, the theory of the competitive firm gives us only that $\partial A^i/\partial \bar{P}^i \geq 0$.

It is instructive to examine in a very simple case the properties of the supply function when it is not linear. Since $\bar{P} = MC\ (A)$ represents the inverse supply function where MC is marginal cost, the supply function is given by $A = MC^{-1}(\bar{P})$. Since $\partial^2 A/\partial \bar{P}^2 = -MC''(A)/[MC'(A)]^3$, it follows that if marginal cost is convex ($C''' > 0$), then the supply function is concave.

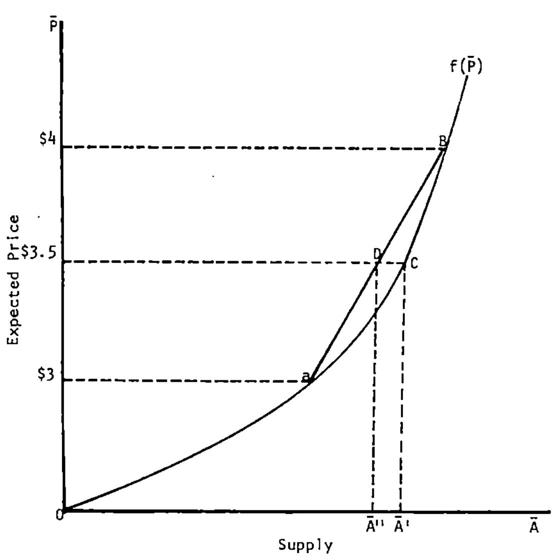

Figure 1. Supply effects of diverse expectations

The marginal cost function is concave when the cost of an additional unit of output increases at an increasing rate. In general, this will occur when production capacity is strictly limited, when strongly diminishing returns are present in the underlying production function, or if one or more important inputs are inelastic in their supply.

Concluding Comments

It is clear that the above reasoning can be applied to a wide variety of problems in economics. For example, permanent income in consumption theory may be uncertain. Its dispersion can affect total consumption. In any case, the purpose of this paper is to explore the implications of aggregation when something in the environment is random. This randomness leads to diverse *ex ante* anticipations. Though the risk-neutral case is explored here, similar results follow for a risk-averse firm. It is particularly interesting, however, that risk neutrality under price uncertainty yields results similar to the supply response analysis under risk (e.g., Just) where variability is negatively correlated with total acreage of a crop (*ceteris paribus*). An interesting area of future research may involve the relationship between the level and dispersion of subjective expectations and socioeconomic variables (e.g., Binswanger). Such information, coupled with some knowledge of the curvature of the supply functions, may help us interpret aggregate supply phenomena in new and useful ways.

On Implicit Forms of Multiproduct-Multifactor Production Functions

Ron C. Mittelhammer, Scott C. Matulich, and D. Bushaw

A quest for generality in economic analysis appears to underlie the long tradition of the use of implicit functions. However, insufficient attention is given to weaknesses and limitations of implicit functions as they are traditionally used (e.g., Cohen and Cyert, Hadar, Henderson and Quandt, Malinvaud, Naylor, Naylor and Vernon, and Samuelson, among others). Careless use of implicit functions can result in faulty analysis. In particular, clarification of these limitations is needed, especially as they pertain to the study of multiproduct-multifactor (MP-MF) production processes.[1]

This paper is a rigorous examination of certain issues regarding implicit functions and MP-MF production processes. Because any relation that explicitly determines one argument as a function of the remaining arguments can be written in implicit function form, our results also apply to explicit function representations of MP-MF production. The functions examined here are continuously differentiable and can be used as production feasibility constraints in a Lagrangian or Kuhn-Tucker analysis of the MP-MF firm.

The theory of MP-MF production is relevant in the conceptualization of resource allocation problems throughout agriculture. For example, few important real-world analyses of agricultural production or marketing operations are single product in nature. In fact, in his extensive literature review on production efficiency in agricultural processing and marketing, French states "multiple outputs are effectively the rule rather than the exception." Similarly, MP-MF theory is prominent in the study of environmental and natural resource problems involving technological externalities. Despite the importance of the theory, it appears that work to date is a collection of special cases of a potentially more general theory. It is our hope that this paper will stimulate a reexamination of MP-MF production theory.

Single-Equation, Implicit Function Representations

Let $F(Z_1, \ldots, Z_p, X_1, \ldots, X_n)$ be a continuous real-valued function defined on the nonnegative orthant in $n + p$ space. Equation (1) is assumed to represent a MP-MF production process relating inputs $(X_1, \ldots, X_n)$ and outputs $(Z_1, \ldots Z_p)$, e.g., see Hadar, Henderson and Quandt, Hicks, Naylor, Naylor and Vernon, Samuelson. Here,

$$(1) \qquad F(Z_1, \ldots, Z_p, X_1, \ldots, X_n) = 0,$$

and will be referred to as the single-equation, implicit function representation (SEIFR) of MP-MF production.

It is generally assumed either explicitly or implicitly that, in a certain domain, F is continuously differentiable with respect to all of its arguments and that the first-order partial derivatives of F are nonzero. In this relevant domain, the partial derivatives $\partial F/\partial Z_i$, $i = 1, \ldots, p$ are assumed to be all of one sign, while the partial derivatives $\partial F/\partial X_j, j = 1, \ldots, n$ are assumed to be all of the opposite sign. Some far-reaching implications of these apparently innocuous assumptions are identified in the following theorem and the discussion that follows.

THEOREM 1. *Under the assumption that all first-order partial derivatives of* F *exist and are nonzero in a certain domain, a production process represented by*

$$(2) \qquad F(W_1, \ldots, W_m) = 0$$

is such that every differentiable local solution for every W_j depends actively on all other W_i, $i \neq j$, in the sense that all $\partial W_j/\partial W_i \neq 0$.

Proof. Let the function F have the assumed properties in a certain domain. Then, if $W_j = \psi_j(W_1, \ldots, W_{j-1}, W_{j+1}, \ldots, W_m)$ is a differentiable local solution for W_j on some neighborhood N, $F[W_1, \ldots, W_{j-1}, \psi_j(W_1, \ldots, W_{j-1}, W_{j+1}, \ldots, W_m), W_{j+1}, \ldots, W_m] = 0$ throughout N. Then, for $i \neq j$, $(\partial F/\partial W_j)(\partial\psi_j/\partial W_i) + \partial F/\partial W_i = 0$ on this neighborhood. Hence, $\partial W_j/\partial W_i = \partial\psi_j/\partial W_i \neq 0$. That is, every local solution of (2) for W_j depends actively on all other W's. The result holds for all j. Q.E.D.

Applying Theorem 1 to equation (1) results in marginal products $\partial Z_i/\partial X_j$, marginal rates of product transformation (MRPT) $\partial Z_i/\partial Z_j$, and marginal rates of technical substitution (MRTS), $\partial X_i/\partial X_j$, all being nonzero. Furthermore, under the assumption

Ron C. Mittelhammer and Scott C. Matulich are assistant professors of agricultural economics, and D. Bushaw is a professor of mathematics, Washington State University.

Special thanks from the authors go to LeRoy Rogers and the College of Agriculture's administration, Washington State University, for their continuing support of basic research on theoretical issues relevant to the study of agricultural economics.

[1] Dano gives one of the most complete presentations of multiproduct-multifactor production. While he recognizes several limitations embodied in implicit functions, his treatment is not as clear and rigorous as deserved.

of continuous differentiability, the implicit function theorem guarantees the existence of these derivatives in the relevant domain, and the simple implicit function rule of the calculus can be used everywhere in that domain to find derivatives between the arguments of F as

$$(3)\quad \begin{aligned} \partial Z_i/\partial X_j &= -(\partial F/\partial X_j)/(\partial F/\partial Z_i), \\ \partial Z_i/\partial Z_j &= -(\partial F/\partial Z_j)/(\partial F/\partial Z_i), \text{ and} \\ \partial X_i/\partial X_j &= -(\partial F/\partial X_j)/(\partial F/\partial X_i). \end{aligned}$$

The assumption that $\partial F/\partial Z_i$ and $\partial F/\partial X_j$ are of opposite sign for any $i = 1, \ldots, p$ and $j = 1, \ldots, n$ assures [from (3)] that marginal products are positive, $\partial Z_i/\partial X_j > 0$, MRPTs are negative, $\partial Z_i/\partial Z_j < 0$, and MRTSs are negative, $\partial X_i/\partial X_j < 0$, in the relevant domain.

Given the stated assumptions, the SEIFR (1) portrays a very restrictive model of MP-MF production—one in which each output depends actively on all inputs and other outputs listed as arguments of F. Despite this limitation, authors have referred to representations of the type (1) either explicitly (e.g., Malinvaud, p. 46) or implicitly (e.g., Henderson and Quandt, p. 95) as the general representation of MP-MF production. In fact, the illusion of generality created by (1) has resulted in erroneous analysis in the literature. For example, consider the MP-MF production function presented by Naylor, and again by Naylor and Vernon:

$$(4)\quad F(Z_1, \ldots, Z_p, X_{11}, \ldots, X_{nl}, \ldots, X_{np}) = 0,$$

where X_{ik} is purported to represent the quantity of the ith input used in the production of the kth output, and F is assumed to be continuously differentiable with nonzero derivatives in the relevant domain. The explicit distribution of inputs among the various outputs implied by double subscripting in (4) is meaningless; from Theorem 1, a production process characterized by such an explicit distribution of inputs cannot be represented by (4) under the stated assumptions. Each of the p output levels could be directly affected by changing any of the input levels, regardless of their subscripting. Attempts by Naylor, and Naylor and Vernon to force explicit distribution of inputs to outputs by use of a SEIFR, such as (4), were futile under the stated assumptions.

Samuelson (p. 236) suggested that any number of independent constraints on input-output combination could be represented by a single equation $F = 0$. For example, a production relation (1) with the specific form,

$$(5)\quad F(Z_1, Z_2, X_{11}, X_{21}, X_{12}, X_{22}) = [g_1(Z_1, X_{11}, X_{21})]^2 + [g_2(Z_2, X_{12}, X_{22})]^2 = 0,$$

is equivalent to the pair

$$(6)\quad \begin{aligned} g_1(Z_1, X_{11}, X_{21}) &= 0, \\ g_2(Z_2, X_{12}, X_{22}) &= 0, \end{aligned}$$

where Z_1 and Z_2 clearly depend (implicitly) only on (X_{11}, X_{21}) and (X_{12}, X_{22}), respectively. Giving little attention to this issue, Samuelson dismissed such a representation as "trivial." Trivial or not, there is a compelling practical reason for not using this representation—it would require relaxing the traditional assumption of nonzero partial derivatives. In fact, any such representation with F continuously differentiable necessarily results in grad **F**, the gradient vector of F, vanishing wherever $F = 0$. Subsequent use of Lagrangian and Kuhn-Tucker methods is invalidated and the implicit function rule is rendered inoperable. The vanishing of grad **F** is proved as a special case of theorem 2.

THEOREM 2. *Suppose $F_1(W_1, \ldots, W_m), \ldots, F_q(W_1, \ldots, W_m)$ are all continuously differentiable on a domain D, and that there exist $p > q$ independent*[2] *differentiable functions $g_1(W_1, \ldots, W_m), \ldots, g_p(W_1, \ldots, W_m)$ on D such that $g_1 = \ldots = g_p = 0$ at every point of D where $F_1 = \ldots = F_q = 0$. Then, if J is the Jacobian matrix $\partial(F_1, \ldots, F_q)/\partial(W_1, \ldots, W_m)$, we have rank $J < q$ wherever $F_1 = \ldots = F_q = 0$.*

Proof. Suppose that $F_1, \ldots, F_q, g_1, \ldots, g_p$ satisfy the hypotheses. Then $q < m$, for in the contrary case we would have (at every point of D) the $p > q \geq m$ linearly independent m-vectors grad $g_1, \ldots,$ *grad* $\mathbf{g}_p$, which is impossible.

Now let $\bar{W} = (\bar{W}_1, \ldots, \bar{W}_m)$ be a point of D at which $F_1 = \ldots = F_q = 0$, and suppose rank $J = q$ (clearly rank $J \leq q$) at $\bar{W}$. For concreteness, suppose that the left-most $q \times q$ submatrix of J, $\partial(F_1, \ldots, F_q)/\partial(W_1, \ldots, W_q)$ is nonsingular at $\bar{W}$. Then, by the implicit function theorem, there exists a differentiable local solution (near $\bar{W}$) of $F_1 = \ldots = F_q = 0$ for $W_1, \ldots, W_q$:

$$(7)\quad \begin{aligned} W_1 &= f_1(W_{q+1}, \ldots, W_m), \\ &\;\;\vdots \\ W_q &= f_q(W_{q+1}, \ldots, W_m). \end{aligned}$$

Then, for all $i = 1, \ldots, p$,

$$(8)\quad \mathbf{g}_i[f_1(W_{q+1}, \ldots, W_m), \ldots, f_q(W_{q+1}, \ldots, W_m), W_{q+1}, \ldots, W_m] = 0,$$

and therefore, for $k = q + 1, \ldots, m$,

$$(9)\quad \sum_{j=1}^{q} \frac{\partial \mathbf{g}_i}{\partial W_j} \frac{\partial f_j}{\partial W_k} + \frac{\partial \mathbf{g}_i}{\partial W_k} = 0.$$

In other words, each of the vectors grad $\mathbf{g}_i$ (at $\bar{W}$) satisfies the equation (grad $\mathbf{g}_i)M = 0$, where M is the $m \times (m - q)$ matrix

[2] In the usual sense that the row gradient vectors grad $\mathbf{g}_1, \ldots,$ grad $\mathbf{g}_p$ are linearly independent at every point of D.

$$\begin{bmatrix} \partial f_1/\partial W_{q+1} & \dots & \partial f_1/\partial W_m \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \partial f_q/\partial W_{q+1} & \dots & \partial f_q/\partial W_m \\ \hdashline 1 & 0 \dots & 0 \\ 0 & 1 \dots & 0 \\ 0 & 0 \dots & 1 \end{bmatrix},$$

whose rank is $m - q$. Thus the solution space of $(\text{grad } \mathbf{g}_i)M = 0$ has dimension q, so the $p > q$ vectors grad $g_1, \dots,$ grad g_p must be linearly dependent, in contradiction to the assumption. Therefore, $\partial(F_1, \dots, F_q)/\partial(W_1, \dots, W_q)$ is singular. The choice of the $q \times q$ submatrix of J was arbitrary, so rank $J < q$—that is, J has less than full row rank. Q.E.D.

If one equation is used to represent the production process as in (1) or (4) and to force more than one independent functional constraint on the arguments of F, as in (5), then Theorem 2, with $q = 1$ and $p > q$, implies that the Jacobian (which in this case is the row vector grad $\mathbf{F}$) will have zero rank Thus grad $\mathbf{F}$ must be the zero vector. Unfortunately, Lagrangian and Kuhn-Tucker conditions are no longer necessary conditions for optimality in a problem having $F = 0$ as a constraint since, in the case at hand, the Jacobian matrix of the constraint functions will have the zero row grad $\mathbf{F}$ as one of its rows, and thus will be less than full row rank.[3] In addition, with grad $\mathbf{F} = [0]$, the useful implicit function rule [e.g., see Henderson and Quandt, Chiang, and recall (3)] cannot be used to define derivatives anywhere.

Unless it were completely unavoidable, it would seem that most economists would prefer not to invalidate the familiar Lagrangian or Kuhn-Tucker methods, and to maintain the availability of other useful tools of the calculus in the general functional representation of MP-MF production. Fortunately, such a representation of MP-MF production is available, having the ability to depict processes other than those for which each output is affected directly by the levels of all inputs and other outputs. This generalization is examined in the next section.

Vector-Equation, Implicit Function Representation

In this section we present the canonical form of the vector-equation, implicit function representation (VEIFR) of MP-MF production. More than one independent functional constraint on input-output combinations can be accommodated without invalidating Lagrangian or Kuhn-Tucker methods. However, derivatives between problem arguments will generally no longer be derivable using the simple implicit function rule method, but will require a more general method of derivation. In addition, the interpretation of these derivatives generally differs from traditional interpretations.

The VEIFR of MP-MF production is

$$(10) \quad \begin{aligned} &F_1(Z_1, \dots, Z_p, X_1, \dots, X_n) = 0, \\ &\qquad \cdot \\ &\qquad \cdot \\ &\qquad \cdot \\ &F_r(Z_1, \dots, Z_p, X_1, \dots, X_n) = 0, \\ &\qquad r \leq n + p. \end{aligned}$$

Each F_i is assumed continuously differentiable, and some $(r \times r)$ submatrix of the $r \times (n + p)$ Jacobian matrix of (10) is nonsingular in the relevant domain.

The VEIFR can be written more compactly in vector function form as

$$(11) \quad \underset{(r \times l)}{F(Z, X)} = \underset{(r \times l)}{[0]} \text{ s.t. } r \leq n + p \text{ and } \rho(J) = r,$$

where

$$J = [\partial F/\partial Z \ \vdots \ \partial F/\partial X],$$

$$\partial F/\partial Z = \begin{bmatrix} \partial F_1/\partial Z_1 & \dots & \partial F_1/\partial Z_p \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \partial F_r/\partial Z_1 & \dots & \partial F_r/\partial Z_p \end{bmatrix},$$

$$\partial F/\partial X = \begin{bmatrix} \partial F_1/\partial X_1 & \dots & \partial F_1/\partial X_n \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \partial F_r/\partial X_1 & \dots & \partial F_r/\partial X_n \end{bmatrix},$$

$Z = (Z_1, \dots, Z_p)$, $X = (X_1, \dots, X_n)$, and $\rho(J) = r$ states that the rank of J is r in the relevant domain.

Up to $r = n + p$, independent constraint equations can be accommodated in this mathematical representation of production. The full complement of input and output variables need not appear as arguments of all r-functions in the representation; each is listed as an argument of all functions for convenience only. An argument may be effectively deleted from a function when the derivative of the function with respect to the argument is assumed to be identically zero. Since $F(Z, X)$ is assumed continuously differentiable, and because $\rho(J) = r$, there is nothing inherent in the VEIFR that would invalidate the Lagrangian or Kuhn-Tucker conditions in an economic optimization problem using the VEIFR of MP-MF production as a feasibility constraint.

When $r > 1$, interpretations of derivatives between arguments of F and methods for deriving them can be troublesome. For simplicity and con-

[3] Full row rank of the Jacobian matrix of the constraint functions is a requirement for Langrangian and Kuhn-Tucker conditions to be necessary for characterizing optimal solutions. This is a version of the constraint qualification often discussed in conjunction with Kuhn-Tucker methods. In particular, in problems having both equality and inequality constraints, the Jacobian matrix of interest consists of the gradient vectors of the functions involved equality constraints, and the gradient vectors of the functions involved in binding inequality constraints. For further details, see Bazaraa and Shetty, chapter 5.

sistency with the notation of the theorems rewrite (1) as

$$F_1(W_1, \ldots, W_m) = 0$$
$$(12) \qquad \vdots \qquad\qquad \vdots\ ,$$
$$F_r(W_1, \ldots, W_m) = 0$$

($r \le m$). Suppose we wish to assign a meaning to $\partial W_i/\partial W_j$ at a point $\bar{W} = (\bar{W}_1, \ldots, \bar{W}_m)$ where the equations (12) are satisfied. This ordinarily would be taken to mean the rate of change in W_i when W_j changes and all the other entries in W are held fixed. However, it may be impossible to hold $m - 2$ of the arguments in (12) fixed without forcing the other two to remain fixed also—or violating (12). For example, let $W_1 - W_2 = 0$, $W_2 - W_3 = 0$. As soon as the value of any one argument is fixed, so are those of the others.

A more subtle attack on the problem uses the implicit function theorem. Again, assume that the functions $F_k (k = 1, \ldots, r)$ are continuously differentiable and that their Jacobian matrix at $\bar{W}$ has rank r. Suppose there exist $r - 1$ indices $k_2, \ldots, k_r$ between 1 and m inclusive, not including i and j (this implies $r < m$), such that the $r \times r$ submatrix M of the Jacobian matrix corresponding to the variables $W_i, W_{k_2}, \ldots, W_{k_r}$ is nonsingular at $\bar{W}$. To make the rest of the discussion more specific, but not less general, we shall assume $i = 1, k_2 = 2, \ldots, k_r = r$, and $j = m$. Then, on some neighborhood of $(\bar{W}_{r+1}, \ldots, \bar{W}_m)$ in $(m - r)$-space, the equations (12) may be solved uniquely for $W_1, \ldots, W_r$:

$$W_1 = \Theta_1(W_{r+1}, \ldots, W_m),$$
$$(13) \qquad \vdots \qquad \vdots$$
$$W_r = \Theta_r(W_{r+1}, \ldots, W_m),$$

where the continuously differentiable functions Θ_k satisfy $\Theta_k(\bar{W}_{r+1}, \ldots, \bar{W}_m) = \bar{W}_k (k = 1, \ldots, r)$. In particular, $\partial W_i/\partial W_j$ (equal to $\partial W_1/\partial W_m$) may now be unambiguously interpreted as the value of $\partial\Theta_1/\partial W_m$ at $(\bar{W}_{r+1}, \ldots, \bar{W}_m)$. This derivative also may be found directly by differentiating implicitly in (12) with respect to W_m, treating $W_{r+1}, \ldots, W_m$ as the independent variables, and solving the resulting linear equations, perhaps by Cramer's rule. The assumption that the submatrix M is nonsingular guarantees that there is a unique solution. This procedure might naturally be described as the generalized implicit function rule.

The point, however, is that the interpretation of $\partial W_i/\partial W_j$ obtained in this way is not as unambiguous as it may at first appear, because it depends, in general, on the choice of the indices $k_2, \ldots, k_r$. That this dependence can be genuine is illustrated by the following simple example: Let $r = 2$, $m = 4$,

$$F_1(W) = W_1 + W_2 - W_3 - W_4,$$
$$F_2(W) = W_1 + 5W_2 - 2W_3 - 3W_4,$$

and $\bar{W} = (1, 1, 1, 1)$. All 2×2 submatrices of the Jacobian matrix are nonsingular. Then depending upon whether k_2 is chosen to be 2 or 3, the generalized implicit function rule yields ½ or -1 as the value of $\partial W_1/\partial W_4$ at $\bar{W}$.

Under the not untypical circumstances just exemplified, one might use a symbol such as $\partial W_i/\partial W_j|(W_{k_2}, \ldots, W_{k_r})$ to distinguish the different possible interpretations of the partial derivative. Each depends on the choice of variables that are treated as dependent [implicitly defined by (12)] along with W_i. These derivatives might reasonably be called conditional partial derivatives.

In the case $r = 1$, the ordinary implicit function rule yields at most one value of $\partial W_i/\partial W_j$, so the problem we have just discussed does not arise. In general, as many as $(m - 2)!/[(r - 1)!(m - r - 1)!]$ values may be produced by the generalized implicit function rule; just how many depends on which $r \times r$ submatrices of the Jacobian matrix are nonsingular.

Additional properties and possible uses in economics of the conditional partial derivatives await further study. For the purposes of this paper, it is sufficient to have observed that they arise naturally.

Of course, the proliferation of conditional derivatives can be avoided by placing more stringent assumptions on the VEIFR. In his seminal work on the theory of the firm under MP-MF production, Pfouts assumes that the MP-MF production relation is a collection of p technically unrelated production functions,

$$F_1(Z_1, X_{11}, \ldots, X_{n1})$$
$$(14) \qquad \vdots$$
$$F_p(Z_p, X_{1p}, \ldots, X_{np})$$
$$= Z_1 - f_1(X_{11}, \ldots, X_{n1}) = 0,$$
$$\vdots$$
$$= Z_p - f_p(X_{1p}, \ldots, X_{np}) = 0.$$

The Pfouts model places rigid assumptions on the entries in the J matrix that result in unique marginal products, $\partial Z_j/\partial X_{ij}$, and unique MRTs, $\partial X_{ij}/\partial X_{kj}$, being defined. All other derivatives vanish.

The specific VEIFR (14) has the property that input quantities are explicitly allocated to the production of specific outputs, which was a property that the debilitated analysis of Naylor, and of Naylor and Vernon, was attempting to incorporate. Their Kuhn-Tucker analysis could be salvaged, *mutatis mutandis*, if the p-entry VEIFR (14) were substituted for their SEIFR (4) of MP-MF production. Theorem 2 makes clear that no less than p-equations could be utilized in the representation if Kuhn-Tucker methods were to be subsequently utilized, as their analysis requires.

Conclusions

The results of this paper indicate that the apparent generality of the SEIFR of MP-MF production is only an illusion when a few traditional assumptions concerning differentiability of F and nonvanishing of partial derivatives are added as properties of the function. A VEIFR was examined which is more versatile. However, the VEIFR presents new problems in the derivation and interpretation of derivatives usually viewed as marginal products and rates of product transformation and technical substitution.

Twenty years after Pfout's seminal work it appears the profession has yet to provide a general Lagrangian or Kuhn-Tucker analysis of the theory of the firm under MP-MF production. Work to date seems to be a collection of special cases of a potentially more general theory.

Subjectivity in *Ex Ante* Research Evaluation

C. Richard Shumway

This essay is a critique of research evaluation research. The argument has three main points. First, considerable evidence exists that agricultural research conducted during the era when projects were chosen by diffuse selection systems yielded extraordinarily high returns. Second, it is not obvious that formalized, quantitative, and centralized selection models can be expected to produce higher contemporary returns than decentralized informal mechanisms. This is because all *ex ante* evaluations are intrinsically subjective, regardless of the technique used. Third, the extreme uncertainty surrounding the nonrepetitive, new-knowledge production function further limits the potential of the sophisticated selection procedures. Perhaps of greater importance, however, are the high costs imposed by these procedures in terms of scientists' time, morale, and "artistic" research tool decay.

Purpose of Research Evaluation

Partially in response to the increasingly heavy pressure from federal and state governments for more detailed planning, evaluation, and accountability of public research resources and partially out of a basic academic interest among diverse scientists, much effort in recent years has been invested in devising new methods for evaluating public agricultural research. To wit, three symposia have been devoted to the subject, resulting in the publication of two books (Fishel; Arndt, Dalrymple, Ruttan) and a forthcoming proceedings of the most recent conference.[1]

Reasons for wanting to evaluate research range from measurement of the historical rate of return for research investments to assessment of the influence of various organizational participants on research selection and conduct. However, just as the many and diverse intermediate objectives of economic research ultimately funnel into the overriding end goal of improving predictive performance, so the major objective of research evaluation research condenses to improving predictions of costs and benefits of future research. The ultimate practical objective of all this work is purely *ex ante*, i.e., to provide relevant information for future funding decisions. Determining the productivity of past investments would be mainly academic, since those costs are sunk, except as information is provided, which is also relevant for making variable cost (i.e., present and future) decisions.

Do We Need Formal *Ex Ante* Analysis?

Ex ante evaluation of research alternatives is not a new concept. It has always been conducted in some fashion at one or more levels in the research organizational hierarchy. Historically, the major assessment of project alternatives has been made by the individual scientist acting as an entrepreneur on behalf of his own professional life. Administrators have reviewed proposals submitted by scientists and approved, disapproved, or modified them, but the major administrative roles have been more in trying to increase total funding and in selecting scientists who would be with the organization for extended periods than in selecting individual projects. Of course, the role of administration varies from organization to organization, but few have implemented formal, systematic evaluation procedures for quantitatively measuring the worth of one research area against another.

The justification for proposing a change in the way *ex ante* research evaluation is conducted must ultimately rest on one of the following perceptions: (*a*) the current system is not working well; or (*b*) some evidence exists that even though the current system is working well, it could do significantly better with a change.[2] Let us investigate briefly whether there are sufficient grounds for either perception in agricultural research.

Importantly, the historical rate of return on agricultural research investments provides valuable information relevant to the first possible justification for change. Although some assumptions underlying the various models can be challenged and some of the data used are disquietingly shallow, the high rate-of-return estimates are profoundly robust.

C. Richard Shumway is a professor of agricultural economics, Texas A&M University, and visiting scholar, Department of Economics, Harvard University.

Technical Article No. 16033 of the Texas Agricultural Experiment Station.

The author is indebted to Bruce Beattie, John Hopkin, Dudley Smith, Willis Peterson, and an anonymous *Journal* reviewer for significant helpful suggestions on an earlier draft of this paper.

[1] Symposium on Methodology for Evaluation of Agricultural Research, Minneapolis, May 1980.

[2] A reviewer suggested a third and perhaps the most common reason for proposing a change in *ex ante* research evaluation—budget appropriators insist on a change in the evaluation process before they will appropriate. Actually this is merely a symptom that the appropriators have one of the two perceptions identified in the text.

Nearly all studies have estimated a historical rate of return to agricultural research investments in excess of the average return on industrial capital investments (see Evenson, Waggoner, Ruttan, p. 1103). This is true not only for studies of aggregate U.S. agricultural research investments, but also of U.S. regional investments, foreign investments, and commodity-specific investments. Consequently, unless equity costs of such research have been extremely high, the only plausible conclusion from the rate-of-return studies is that there has been general underinvestment in agricultural research.[3] Some evidence exists that the rate of return on aggregate U.S. agricultural research investments may be decreasing with time (see Peterson and Fitzharris, p. 78; Evenson, Waggoner, Ruttan, p. 1103), but the most recent estimates are still in excess of 20% per year. Thus, underinvestment in agricultural research is still apparent.

With such high estimates of historical rates of return, it is difficult to argue logically that the seemingly loose *ex ante* evaluation procedures used in the past have not worked well. So the first justification for arguing a need for change must be dismissed.

Arriving at a clear conclusion concerning the second justification is not so easy. It is a truism that we can always do better. Unfortunately that truism has little practical value. We are not working with optimum versus suboptimum, because in *ex ante* evaluation the optimum is indeterminate. There is simply too much uncertainty in the nonrepetitive, new-knowledge production function. The primary issue in our evaluation of *ex ante* evaluation procedures is not whether some bad projects have been funded in the past or whether more will be in the future. It is fundamentally whether we will decrease the errors and increase the total payoff from research efforts by changing the evaluation procedure.

Arguments in favor of a change often focus on the benefits of "systematic" evaluations and greater "objectivity." Many of the proposed alternative evaluation procedures are clearly systematic. They permit categorizing, ordering, comparing, and summarizing data in ways that are internally consistent and thus systematic. The question is whether they permit any greater objectivity than the evaluation methods used historically.

Role of Objective Data in *Ex Ante* Analysis

Objectivity is obviously preferred to subjectivity easily defended. It is easier to convince another person of the truth of objective rather than subjective observations. Since the future is unknown and highly uncertain, the only objective data are historical observations. Because methods for measuring the historical research performance have received considerable attention, the use of such historical data is a logical place to begin. If it is possible to correlate with confidence historical research performance with future research payoff at a very micro level, our evaluation procedures could introduce a measure of objectivity that would increase their administrative value considerably.

Within the profession, there is considerable expectation that a scientist who has proved to be highly productive in the past is a good risk for future investments of support funds. Although examples to the contrary abound, there is strong sentiment that historical performance of a scientist is a useful tool for predicting future productivity. Thus, funding agencies continue to invest a large share of their money with proven researchers. There appears to be little risk that investments in a Samuelson or a Friedman will not pay rich dividends.

Unfortunately, no research organization is made up of all Samuelsons and Friedmans. Few have even one. How then can these administrators take advantage of historical information to help them determine which additional research areas to promote and which to reduce?

I have previously proposed a set of four sufficient conditions that would permit the use of historical information at the research area level in objectively predicting future payoff (Shumway, p. 192). The conditions are: (*a*) Proposed projects are competitive for available resources. (*b*) Research technology used on each historical and proposed project is of comparable quality for its time. (*c*) The production function for new knowledge discovery is characterized by an S-shaped (stages 1 and 2 only) production function. (*d*) Each project represents a small movement along the knowledge production function.

These four conditions are sufficient to establish an orderly relationship between past and future research payoff. I have made a defense for each condition, but the defense for conditions (3) and (4) remains the weakest. The likelihood that the new knowledge production function is anything close to a smooth S-shape seems quite low. A less restrictive concave production function would still be sufficient, but it would have to be reasonably smooth. It is the smoothness property that is most

even most, of the applied research of any state or federal agricultural research unit is quite low.[4]

It is true, for example, that breakthroughs in hybrid corn research have had important effects on hybrid grain sorghum and wheat research. But what has been the payoff from recent genetic research on corn? The marginal physical product of genetic research on corn could be characterized more as a few important blips (e.g., male sterile techniques, upright leaves, and high lysine varieties) and one huge blip (hybrids) than as anything close to a smooth function.

While hard scientific data on the subject are lacking, a few case studies document the need to be cautious about overestimating the value of objective data for the *ex ante* funding decision. It appears unlikely that my sufficient conditions will prove very useful. Unless someone identifies another set with a considerably higher likelihood of being met, objective data will continue to play a minor role in *ex ante* research evaluation.

Many casual observers, including some research administrators and even some analysts, mistakenly attribute objectivism to certain evaluation techniques. The fallacy is in equating objectivity with quantifiability. Many techniques do use quantitative and/or qualitative inputs and provide quantitative evaluation outputs, but all *ex ante* research evaluation procedures are inherently subjective. The only difference is where subjectivity enters and how it is processed.

With Q-sort, subjectivity is imposed by the administrator at the highest level of abstraction in grouping projects into categories of similar overall worth. With scoring models, subjectivity determines the specification and weighting of criteria and the categorization of each project relative to each criterion. Only the computation of the overall score proceeds in an "objective" fashion (Moore and Baker). With *ex ante* benefit-cost and rate-of-return estimates, subjectivity is also inherent in the estimates of both research benefits and investment costs (e.g., Araji, Sim, Gardner). The predicted benefit-cost ratio and the rate-of-return estimate are quantified, but they are nonetheless subjective. Formalized optimization models (e.g., Shumway and Hwang) rely on subjective evaluations of the relative importance of objectives, expected achievement of objectives, probability of success, and expected cost. Even Rausser et al.'s recently proposed four-stage evaluation procedure is based almost exclusively on subjective data.

The only contributions any of the formal *ex ante* evaluation techniques can make, whether used at the micro level of the project or at some aggregated level, are to (*a*) permit a formalization of the role of subjectivity, (*b*) suggest collection of objective information on which to base subjective assessments, (*c*) insert subjectivity in forms that are most natural, and (*d*) process subjective data systematically in order to feed back information relevant to the funding decision. They cannot make objective outputs from subjective inputs, no matter how precise and elegant they appear. Consequently, the legitimate role of subjectivity in *ex ante* evaluation needs to be recognized clearly and respected.

Assessment of Formal *Ex Ante* Evaluation Procedures

It is evident that many of the formal evaluation procedures are systematic. It is not clear that they are any more conducive to objectivity than the commonly used methods of evaluation. The fact that systematic evaluation procedures have been recommended to research administrators for at least fifteen years and few have implemented them is strong *prima facie* evidence that their current costs outweigh their perceived benefits.[5]

A quaint but relevant comparison is that if a car is broken, the mechanic tries to fix it. However, if it is running well and is getting better gas mileage and emits fewer pollutants than other comparable cars, he leaves it alone. He does not overhaul it until he has some evidence that it will then perform better.

The agricultural research establishment is not perfect, but it has performed well in the past without formal *ex ante* evaluation techniques. Further, there is no convincing evidence it will perform any better in the future with them. A heavy burden of proof that administrators need sophisticated and formalized *ex ante* research evaluation systems still rests upon the system developers.[6]

Administration-Scientist Synergism

It is entirely possible that efforts to develop relevant evaluation techniques have focused on the

---

[4] It is likely that the research production function becomes more stable with increasing aggregation since successes and failures on individual projects tend to average out. However, uncertainty remains great even at the broad research area level, and pressures for more systematic *ex ante* evaluation procedures extend to much lower levels.

[5] This is not to say that such rejection is sufficient evidence to discontinue research on alternative management techniques. The management and information sciences are still in their infancy, and their innovations face generally low rates of adoption in many fields.

[6] I am indebted to Willis Peterson for adding a caution regarding the evaluation procedures used by NSF, NIH, and many other research-funding agencies that are formalized and systematic only in the sense that they rely on formally requested peer reviews. "One should raise the question whether outside evaluators . . . can be expected to give a very good estimate of the probability of success of a project, and if it is successful how much the new knowledge which is produced will be worth to society. Even the evaluation of peers should not be assumed to be superior to the assessment made by the person submitting the proposal. It usually is assumed to be superior, however, because the final decision to fund a project generally is based on peer review and the project author rarely has a chance to reply to the review. If the reviewers do not happen to be working in exactly the same area or if they are partial to a different approach, many potentially successful projects could be rejected."

wrong person. Administrators must make project selection decisions. But the alternatives they select from are formulated mainly by scientists, not by administrators. The organization must have proposals generated by imaginative, capable scientists who are well attuned to the problems of the public and the respective disciplines. Otherwise, administrators have only hollow project selection decisions to make.

A serious potential risk emanates from all the attention given to systematic and rigorous *ex ante* research evaluation. It is possible that greater administrative intervention in project selection will lead to submission of a larger number of proposals but with lower quality research to be conducted on all of them. The larger number of proposals permits administrators to exercise their responsibility of decision making. But, will the quality and quantity of research conducted by the organization be as great as when performed by well-motivated scientific entrepreneurs unencumbered by either the paper requirements or the annoyance of organizational demands for *ex ante* evaluation and *ex post* accountability?

Unless the research organization is going to change scientists more often than any do now, the only relevant research alternatives are those that can be pursued by existing scientists plus a few new ones. Therefore, the appropriate place to begin the evaluation process is with the scientist. How can this entrepreneur be helped to select projects with high potential payoff?

Problem selection is generally the most important and most difficult part of inquiry. It is important because it delimits the range of investigation and establishes upper limits, although undefined, on the potential payoff of the inquiry. It is difficult largely because there are no formal rules by which scientists can learn to ask significant questions leading to the recognition of significant problems. The ability to formulate important problems whose solution may also help solve other problems is often considered to be a rare gift.

Yet, some relevant guides can be identified to assist this learning process and sharpen the subjective perception of relevance. Sources of valuable signals must be cultivated, rational thought processes must be used in serious evaluation, and subconscious intuition must not be throttled.

Research Priority Signals

Only a weak economic market exists for public research products since few products are sold and most are placed in the public domain at little or no charge to the user. However, an obvious source of research priority signals is still the market system. There is a strong economic market on the resource side of research, i.e., the job market. Bids and offers for particular scientists largely reflect a perception of the relevance, quality, and quantity of their work. While such offers are determined primarily by intermediate research products (i.e., publications), they are proxies for anticipated value of the final products to society.

Market signals also come from the user in the form of legislative support or lack of support for research budgets. If the political processes work smoothly, legislators will reflect the attitudes of a majority of their constituents. Thus, the budget message is an economic signal from the end-product market to research administrators. Administrative priorities in turn become proxies for public preferences.

While these economic signals are important, they are not sufficient for *ex ante* evaluation because either they are not sufficiently specific or they are based on assessments of work already completed. Additional sources of signals need to be cultivated. Strong two-way bridges of communication between research and extension are important to permit flow of current societal priority signals to researchers as well as new knowledge to users. The scientific community has a responsibility also to address problems not yet faced by society and to build the theoretical structure and analytical tools to deal with them when they do occur. Reading, professional meetings, and interaction with other scientists can hone the scientists' perception of such theoretical research priorities.

Project Selection by the Scientist

With good communication among colleagues, competent scientists always will be aware of far more interesting and important research problems than can possibly be addressed. The next challenge is to propose a set of prioritized projects to the administration that the scientist considers to have the highest payoff. It is unlikely that the scientist will find quantitative evaluation models useful for this purpose, but a few simple questions might be helpful. For example:

(*a*) Who is your clientele?

(*b*) What are your priorities as to audience service (e.g., policy makers, researchers, farmers)?

(*c*) To whom is the problem important?

(*d*) To how many is the problem important?

(*e*) How much benefit will the clientele receive if this problem is solved?

(*f*) Do you have the analytical tools to conduct the research?

(*g*) What is the likelihood that your research effort will provide (or at least contribute to) a solution to the problem?

(*h*) What are the expected research costs (money and time)?

(*i*) What are the expected implementation costs?

No weights are suggested. Answers to these or similar questions help to identify weak links in the proposed study and promote communication between scientist and administrator. It is possible that the scientist's answers to questions (*a*) and (*b*) may be different than his administrator would like them to be, but explicitly defining them can be valuable in uncovering differences that could remain undefined

and become a source of confusing interaction between the two.

"Artistic" Considerations

Because identification and pursuit of significant research problems is not an exact science, the role of nonobjective research tools also needs to be addressed. In a recent article, Ladd identified some of the most frequently used, versatile, and valuable research tools, none of which lend themselves to formal incorporation in a quantitative *ex ante* project evaluation model. They include the subconscious mental processes of imagination, intuition, and hunch, the unpredictable role of chance and serendipity, and the stimulating effects on the subconscious and on research efficiency from writing. These artistic tools probably are at least as important to productive research as are the orderly and systematic thought processes. Consequently, whatever procedures are considered to assure *ex ante* evaluation and *ex post* accountability ought to be weighed carefully against any possible negative impact on these valuable research tools.

Conclusions

Five concluding recommendations are drawn from this attempt to elaborate the relevance of subjectivity in *ex ante* research evaluation:

(*a*) Let us be realistic about the contribution formal research evaluation techniques can make. No more should be promised than can be delivered. Quantification is not synonymous with "better." Negative impacts on scientist morale, ambition, and imagination must be weighed carefully against any expected benefits from increasing the planning, evaluation, and accountability functions of the organization.

(*b*) Because the search for new knowledge is laden with heavy risks and many dead ends, it may be unwise for a research organization to establish a single, overriding objective. An individual researcher may be single-minded, but perhaps the organization should deliberately be a little schizophrenic and simultaneously pursue conflicting goals in order to be prepared for changing conditions.

(*c*) The prominent place of subjectivity in *ex ante* evaluation needs formal recognition and respect. Just as quantification does not mean better, neither does it imply objectivity. Any *ex ante* evaluation is intrinsically subjective. Objective historical observations may be relevant, but the linkage between past and future knowledge generation is sufficiently weak to require gross subjective synthesis and assessment.

(*d*) Instead of worrying about dividing an existing pie among many competitive alternatives, let us concentrate on educating administrators how to use historical data relevantly. Historical rate-of-return estimates are sufficiently high and robust to imply that the major deficiency has not been in allocation but in level of overall investment. It seems clear there has been public underinvestment in agricultural research.

(*e*) The role of the individual scientist in *ex ante* evaluation warrants considerably more attention. Without his/her generation of ideas and aggressive pursuit of interesting problems, the research organization would stagnate regardless of the valiant efforts of the administration. The scientist is the first and most important participant in the research evaluation process and is fundamentally concerned with and involved in project selection. Evaluation techniques which do not recognize that crucial linkage or which demand additional effort from the scientist in documentation and accountability for the system's sake are doomed to dismal failure.

Choices and Consequences: Comment

Richard Green and Zuhair A. Hassan

King in his July 1979 presidential address to the Association discussed some problems facing economists in the selection of a proper analytical approach and the evaluation of consequences from these choices for decision makers. To illustrate his points, he cited works by Green, Hassan, and Johnson; and Hassan, Johnson, and Finley. Three areas of major concern were mentioned: (*a*) formulation of hypotheses tests, (*b*) changing elasticities over time, and (*c*) the relationship between price and income elasticities in complete demand systems. In this comment we respond to the first and third problem areas in demand analyses as identified by King. The objective is to place some of the critical statements in perspective. A discussion of changing elasticities can be found in Hassan, Johnson, and Finley, and the subsequent exchange with deJanvry.[1]

The literature contains a number of studies reporting on the estimation of utility-function-based demand systems, such as the indirect addilog model, the translog model, and the linear expenditure system (LES). Each system is not without its limitations, and there are associated costs with choosing any complete demand system. The translog system, for example, is data-demanding since a large number of parameters must be estimated. The LES and the indirect addilog, on the other hand, are derived from additive utility functions. This behavioral restriction implies strong restrictions on substitution possibilities. Of course, the selection of the model must be guided by the benefits and costs weighed in the context of the problem at hand.

The "take-home message" of this discussion is that in applied work, the choice of any model implies certain undesirable consequences for the user. And in particular, in applied demand analyses, whether to use a single-equation approach or a systems approach and which alternative functional representation to employ is a judgmental decision that always leaves the economist in a vulnerable position. The hope is that the authors conducting the research are aware that models are to be used, not believed (Theil, p. vi).

Referring to King's specific criticisms, we consider first the question of proper hypothesis formulation. Instead of testing that the marginal budget shares are equal to zero, King suggests that a more proper test would involve whether the marginal budget shares (MBS) differ from the average budget shares (ABS) at the mean or otherwise specified income levels. This information is already available in the estimated income elasticities since they equal the ratio of the marginal budget to average budget shares. A value of the income elasticity greater than one implies that the MBS is greater than the ABS and a value less than one implies the reverse. Thus, information equal in quality to that provided by King on this hypothesis can be obtained simply by inspection of the magnitudes of the income elasticities. The tests called for, however, require more rigor than is implicit in the data presented. More specifically, standard errors associated with the income elasticities must be calculated, and in some complete demand systems the variances of the sampling distributions of elasticities have not been explicitly derived. An investigation of their statistical reliability through formal tests of significance is then hampered to a large degree.

Perhaps the most serious limitation of the LES, which was pointed out by Deaton, is the approximate relationship of proportionality between income and price elasticities. This property is referred to as Pigou's Law because he was the first one to discover the relationship for additivity demand models. King (p. 845) states that, from this relationship, it can be demonstrated that the LES requires income elasticities to be larger than price elasticities, and the latter must lie between 0 and -1.0. Neither one of these assertions is true. If negative marginal budget shares are allowed—and Deaton (p. 30) does not rule this out a priori, although he recognizes it creates some difficulties—it is possible that negative income elasticities can be obtained that are algebraically less than price elasticities. However, these conditions would imply a violation of the nonsatiety axiom of demand theory (Powell, p. 38). An anonymous reviewer also pointed out that it can be shown that the LES can produce elasticity estimates comparable to Wold and Jureen's rule if some or all of the minimum subsis-

Giannini Foundation Research Paper No. 586.

S. R. Johnson and an anonymous reviewer provided helpful comments on an earlier draft of this comment.

[1] At issue was the question of whether the models were approximations to the true system. Our position was that the models were approximations and that it was of interest to examine possible changes in elasticities implied by the grossness of the approximation. Had we to do this analysis again, we would have used, instead, a variational parameters hypothesis directly assessing the changing elasticities.

tence quantities, γ_i, are negative. In addition, price elasticities in the LES can be greater then one in absolute value if the "minimum subsistence quality," γ_i, is negative. Theory does not rule out a negative value for γ_i, and negative estimates for γ_i have been obtained under certain conditions. But the most important consideration is how serious a consequence does this property of the LES inflict upon empirical results? Does this make the static LES completely unusable for food policy evaluation purposes, as King (p. 846) suggests? Let us explore this question a bit further.

King comments that earlier works of Brandow, Waugh, and George and King found price elasticities for food commodities (necessities) greater than income elasticities for food in accordance with Wold and Jureen's rule. That rule states that income elasticities of necessities are smaller than their price elasticities, whereas income elasticities of luxuries are greater than their price elasticities. Several observations are in order here. First, the earlier works cited by King obtained price and income elasticity estimates using some rather ad hoc procedures. Block additivity was assumed, extraneous estimates were introduced as known with certainty, etc. Consequently, from an econometric viewpoint these earlier estimates might be held suspect, especially as they relate to food groups. Second, Deaton, who is slightly critical of the LES for the "Pigou" relationship, estimates a double-log model using the same data. It is interesting to note (p. 69) that, although the proportionality result is not reflected in the estimated price and income elasticities, he did obtain income elasticities for many commodities that would be considered necessities, including food commodities that were larger than their associated own-price elasticities (pp. 70–77). Many other empirical studies indicate similar conclusions, which implies that Wold and Jureen's rule, although intuitively appealing, is unambiguously true only for the two-commodity case. The rule does not necessarily hold for complete demand systems. In addition, the assumption of additivity is defensible if the arguments of the utility function are taken to be broad aggregates of commodities such as food and clothing, rather than individual commodities such as beef or cheese. A recent article by Klevmarken shows that the LES compared with nonadditive models in terms of goodness of fit, predictions, and comparisons of elasticities.

What is the main conclusion that can be reached from this examination of choices and their consequences in a demand context? We think that the primary one is that in applied demand analysis (or, more generally, applied economic research) any choice of a model has trade-offs. Thus, any policy statements made from the empirical results should be recognized as reflecting the limitations of the theoretical model and the econometric procedures used. This is not to say that applied demand analysis is not useful to policy makers, but rather that research results must be used with knowledge of the assumptions and weaknesses of the methods employed. Finally, we disagree in the specific conclusions reached by King concerning use of additive demand models, especially when limitations of alternative procedures are fully taken into account. We applaud his attempt to be scholarly but feel that he has failed to recognize that all models are but approximations of underlying systems. We should not be surprised that the approximations, likely developed with certain purposes in mind, do not yield desirable characteristics of all features of the system.

Choices and Consequences: Reply

Richard A. King

In their "Comment," Green and Hassan note that the choice of a model involves trade-offs, that model results are to be used rather than believed, and that a single model may not be best for all purposes. These points cannot be stressed too often. However, they raise a number of concerns that warrant further clarification.

Green and Hassan have managed to smoke out the real reason I selected the example of simultaneous demand systems when discussing the general problem of identifying benefits and costs of alternative models. The reason is simply that the results reported by many economists using these models seem implausible to me. I set out to discover why these models produce estimated income elasticities that are consistently higher than the absolute value of direct price elasticities.

The result of this search was to uncover what I believe to be previously unrecognized constraints on elasticities that are inherent in many complete demand system models. Perhaps my explanation of how empirical demand elasticity estimates are constrained in these models was unclear. A more complete explanation of those constraints may help to settle several points at issue. The linear expenditure system (LES) is selected for this purpose.

Consider first the relationship between income and price elasticities. Green and Hassan suggest that the most serious limitation of LES models is the approximate proportionality between the two (Pigou's Law). It is my opinion that constraints on the absolute size of income and price elasticities are more serious in view of the violation of Wold's rule that, in general, price elasticities for necessities should be larger than income elasticities, and price elasticities for luxuries should be smaller than their associated income elasticities.

Green and Hassan state that I was in error in arguing that LES income elasticities must be larger in absolute value than price elasticities. The qualification that must be added to make this a correct statement is that price elasticities are assumed to be nonpositive. In fact, it can be shown that if price elasticities are positive, then income elasticities must be smaller than or equal to price elasticities. This occurs when negative marginal budget shares are encountered for the group in question, implying a violation of the axiom of nonsatiety, as noted by Deaton. That possibility requires a modification of my figure 3c as shown below (figure 1). It is true that all elasticity estimates must lie to the right of the diagonal line AB.

To evaluate LES model constraints on price elasticities, it is necessary to establish appropriate limits on the range of the minimum subsistence quantities, γ_i. The absolute value of price elasticities can be greater than one if γ_i is negative. Although negative values of γ_i are not ruled out on theoretical grounds, it is possible to do so on other grounds. Unless all group expenditure functions pass through the origin (all $E_i = 1$), some will have a positive expenditure axis intercept while others will have a negative intercept. It is the latter that have negative γ_i values over the lowest ranges of income. However, all such values of income are smaller than M_s, the minimum subsistence income. (M_s demarks the level of income above which no group expenditure function lies below the income axis.) Let us rule out the possibility of sales by households, which would allow expenditures on other groups to exceed income, M. This is done by the appropriate identification of M_s and is equivalent to requiring non-negative values of the minimum subsistence quantities, γ_i, as shown in my 1979 paper (p. 842).

We now investigate in more detail the constraints on direct price elasticities. Following Green, Hassan, and Johnson (p. 94), we write the LES individual expenditure function for group i as

$$(1) \qquad p_i q_i = p_i\gamma_i + \mu_i\,(M - \Sigma p_i\gamma_i),$$

where $p_i\gamma_i$ is expenditure on i at minimum subsistence income, M_s, and M is total expenditure $\equiv$ income. Let $M_s = \Sigma p_i\gamma_i \equiv$ minimum subsistence income, and $M_n = M - M_s \equiv$ supernumerary income. We rewrite (1) as

$$(2) \qquad p_i q_i = p_i\gamma_i + \mu_i M - \mu_i M_s.$$

If we combine the first and third terms in (2), we have the expenditure axis intercept term,

$$p_i\gamma'_i = p_i\gamma_i - \mu_i M_s,$$

and the expenditure function (1) can be written as

$$(3) \qquad p_i q_i = p_i\gamma'_i + \mu_i M,$$

where μ_i is the constant marginal budget share such that $0 < \mu_i < 1$ and $\sum_i \mu_i = 1$.

Again following Green, Hassan, and Johnson (table 1, p. 95), we write the LES equation for direct price elasticities as

---

Richard A. King is M. G. Mann Professor of Economics and Business, North Carolina State University, Raleigh.

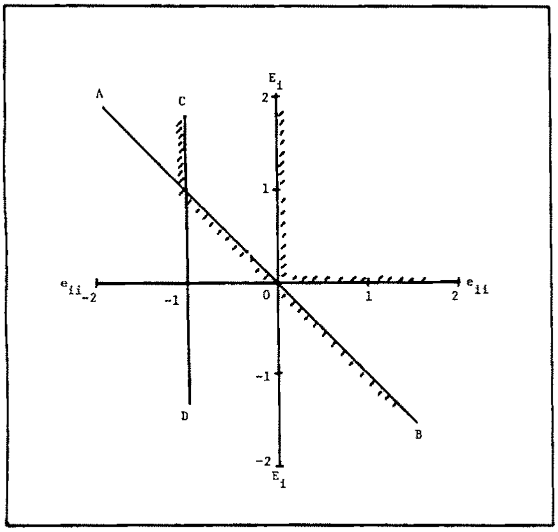

Figure 1. Relation between price elasticities (e_{ii}) and income elasticities (E_i), LES model

$$e_{ii} = -1 + (1 - \mu_i)\,\gamma_i/q_i. \tag{4}$$

Given that γ_i and q_i are non-negative in the relevant range of income, with

$$q_i \geq \gamma_i \text{ and } 0 < \mu_i < 1,$$

it follows that the second term lies in the range

$$0 \leq (1 - \mu_i)\,\gamma_i/q_i < 1.$$

Thus, the direct price elasticities are constrained to lie in the region $-1 \leq e_{ii} < 0$. As M rises, the ratio γ_i/q_i approaches zero and e_{ii} approaches -1. Direct price elasticities thus are constrained to the region between the vertical axis and the line CD (fig. 1).

We next investigate the size of E_i relative to e_{ii}. Changing the sign of e_{ii}, we evaluate the following:

$$E_i \gtrless -e_{ii}. \tag{5}$$

We write (5) as

$$\frac{\mu_i}{w_i} \gtrless 1 - (1 - \mu_i)\frac{\gamma_i}{q_i}, \tag{6}$$

where $w_i = p_iq_i/M$. We rewrite (6) as

$$\frac{\mu_i M}{p_iq_i} \gtrless 1 - \frac{\gamma_i}{q_i} + \frac{\mu_i\gamma_i}{q_i}, \text{ or} \tag{7}$$

$$\mu_i M \gtrless p_iq_i - p_i\gamma_i + \mu_ip_i\gamma_i. \tag{8}$$

But, from equation (1) we know that

$$p_iq_i = p_i\gamma_i + \mu_iM - \mu_i\Sigma p_i\gamma_i.$$

Substituting this relation in (8) produces

$$0 \gtrless p_i\gamma_i - \Sigma p_i\gamma_i. \tag{9}$$

Since $p_i\gamma_i \leq \Sigma p_i\gamma_i$, it follows that

$$p_i\gamma_i - \Sigma p_i\gamma_i \leq 0.$$

Therefore $E_i \geq -e_{ii}$, thus violating Wold's rule for necessities as illustrated in figure 3c of my paper (p. 844). Green and Hassan give no reason for suggesting that increasing the number of commodities would change the finding that LES price elasticities must be smaller than income elasticities and lie between 0 and -1, surely a matter of some interest to users of empirical demand estimates.

We have assumed thus far that each marginal budget share, μ_i, is positive and smaller than one. If equal to zero, it follows that income and price elasticities are equal to zero. If negative, it follows that income elasticity is negative, the corresponding price elasticity is positive [see eq. (4)], and the absolute value of income elasticity is smaller than price elasticity. Changing signs on both sides of (5) reverses the inequality found in equation (9). For obvious reasons, this latter case is of little empirical interest.

Under what circumstances is a simultaneous demand systems model (e.g., indirect addilog, translog, LES) to be preferred over a "sequential" (ad hoc?) estimation method of the Brandow and George-King variety that weaves together bits of information from a variety of sources? The benefits deriving from the first alternative are fairly clear, but users may not recognize fully certain undesirable consequences, other than the need for large data sets, that are incurred in the process, a point that I intended to stress in my Pullman paper. Appeal to the utility function foundation of demand systems models may or may not be persuasive, depending on one's tastes in the matter.

As for appropriate hypotheses, of some interest is the question of whether there is any reason to regard various commodity groups as differing in response to changes in income. The notion that one should substitute an eyeball test of the size of income elasticities reflects a lack of imagination, to say the least. Budget weight is known and standard errors of the marginal budget shares are reported.

Books Reviewed

Goodwin, Geoffrey, and James Mayall, eds. ***A New International Commodity Regime.*** **New York: St. Martin's Press, 1980, 237 pp., $25.00.**

The developing countries proposed an Integrated Commodity Program (ICP) as part of their call for a New International Economic Order (NIEO) at the Special Session of the United Nations General Assembly in Algiers in 1974. The ICP was at the heart of the call for an NIEO. Responsibility for drawing up a proposal was entrusted to UNCTAD. At UNCTAD IV in 1976 approval was given to proceed with explorations for an ICP for ten core commodities (coffee, cocoa, tea, sugar, natural rubber, sisal, cotton, jute, copper, and tin). The integrated dimension was to be provided by a Common Fund (CF) of $6 billion, the primary purpose of which was to finance agreements for the core commodities, and the secondary purpose of which was to undertake a series of activities to aid nonstorable commodities of importance to the developing countries.

This book brings together seven papers on the ICP which grew out of a seminar on the topic sponsored by the Center for International Studies at the London School of Economics and Political Science (LSE) in 1976–78. It attempts to present a broad perspective regarding not only the political and economic aspects of the debate, but also the role of the private sector in the form of international commodity markets and direct foreign international investment. The presentation is verbal, without undue recourse to technical jargon.

This book is divided into two parts. Part I attempts to provide background. Chapter 1, "The Pressures for a New International Commodity Regime" by Mayall (LSE), describes and analyzes the political evolution of the call for an ICP and CF, the anatomy of the Group of 77 (i.e., the developing countries), and the question of legitimacy and management in North/South economic relations. Chapter 2, "The Case for a New International Commodity Regime: Confused Arguments and Unresolved Issues" by Stuart Harris (Trade Policy Research Center, London and Australia National University), summarizes existing international economic arrangements and arguments about the nature of present international commodity markets and the impact of proposed changes. Chapter 3, "The Current State of International Commodity Negotiations" by Alister McIntyre (UNCTAD), briefly describes negotiations on the CF and on individual [illegible] dices consider the nature of international commodity markets for wheat and coarse grains, tin, and copper.

Part II focuses on the industrialized countries' responses to the proposed ICP and CF and on the role of the private sector in the international commodity markets. Chapter 4, "The OECD Industrialized Countries' Response" by Goodwin (University of London), traces the evolution of reactions to the UNCTAD ICP proposal and the underlying causes thereof in the United States, Federal Republic of Germany, United Kingdom, Japan, and (much more briefly) other developed countries. Chapter 5, "The Scope for Co-Cooperation Between Existing Market Institutions and International Commodity Agreements" by James Fry (Commodities Research Unit, London), presents interesting analyses of interaction between commodity agreements and existing spot and future markets (e.g., London Metal Exchange) and how such interactions would constrain and expand the options available to managers of commodity agreements. Chapter 6, "Mineral Exploration and Third World Policy Towards the Mining Industry" by Brian Hindley (LSE), is a thoughtful analysis of the problems in designing contracts between host developing countries and potential mineral explorers and investors in a world of uncertainty and of the costs incurred by a number of developing countries through insisting on contract unenforceability (and thus discouraging subsequent investments) or service contracts (in which they assume all risks). Chapter 7, "Private Sector Investment and Political Risk: A Comparative Study of OPIC and Other Schemes" by Ronald K. Shelp (American International Group), describes recent operations of (largely industrialized government) insurance schemes for political risks for investments in developing countries.

I have reservations about some aspects of this book. At times some of the "facts" do not seem right (e.g., that among the UNCTAD commodities only coffee, cocoa, sugar, and tin have low price elasticities of demand (p. 30) or that Indonesia is among "the more advanced developing nations," p. 225). Sometimes the analysis is not sufficiently updated for a book published in 1980 (e.g., on p. 90 there is reference to the "current price"—for January 1977). The three appendices on "representative commodities" (p. 7) do not include even one of the UNCTAD core agricultural commodities. Occa-

sidered sufficiently in a book which purports to place special emphasis on the role of the private sector.

But despite these reservations, I think that it is a useful book. It generally is well-written, with efforts to integrate the material somewhat across chapters. Several of the chapters are particularly useful in providing a broad perspective on the context of the debate on the ICP and CF and related issues (e.g., those by Mayall, Harris, Goodwin, Fry, and Hindley). The broad perspective which it provides complements well other good recent studies of ICP's, the CF and the NIEO[1] and thus contributes to a better understanding of the issues and possible resolutions in this important area.

Jere R. Behrman
University of Pennsylvania

Guither, Harold D. *The Food Lobbyists: Behind the Scenes of Food and AgriPolitics*. Lexington, Mass.: D.C. Heath Co., 1980, 358 pp., $27.95.

A widely held view in recent years is that a new agenda has evolved for farm and food policy makers. Now, along comes Professor Harold Guither of the University of Illinois to explain that, in addition to a new agenda, there are new actors participating in the policy-making process.

His book, in some ways untraditional for a professor of agricultural economics, with its foreword by Congressman Paul Findley, was written "to identify and briefly describe the many organizations and groups that have had vital interests and concerns about federal government decisions in some phase of agriculture, food production, and distribution in the late 1970's."

After naming the official cast that manages the federal policy-making process, Professor Guither goes on to review a wide range of interests that influence the design and conduct of federal farm and food policies. His presentation, in general, left this reader feeling that the influence of these organizations and groups is growing and may eventually exceed that of the more traditional farm organizations.

An interesting extension of this section is an appendix that lists food- and farm-oriented groups that made contributions to political candidates in 1977–78 through political action committees, the established mechanism for giving financial support to political candidates. Included on the list are the number of candidates supported from each party and the total amount of contributions by each organization. Of some note because of their minimal contributions were the major farm organizations. Of some note because of their sizeable contributions were the dairy cooperatives, the rural electric cooperatives, and, as farmers have long suspected, the boards of trade and mercantile exchanges. The surprise relative to the latter group was the near-balance reported in the number of candidates supported from each major political party.

While the major farm organizations did not appear strong in the contributions area—only the American Farm Bureau Federation had established political action committees—this reviewer was surprised, in some ways pleasantly, by another particular activity carried on by a major farm organization. The National Farmers Union is the sponsor for the federally financed Green Thumb Program which "hires and finds jobs for low income men and women fifty-five years old and older in rural areas." The program, administered for NFU by former Assistant Secretary of Agriculture John Baker until he retired in 1979, was first funded by the Department of Labor in 1974 with $3.6 million. With a growth rate that must set a record for a rural development-type program, it reached $72.2 million in 1979.

While Professor Guither found concern on Capitol Hill over the rapid budgetary growth for this "greenback" program, this reviewer found it interesting for other reasons. During this same period, Land Grant Universities were struggling to keep their academically oriented rural development programs alive. Further, monthly unemployment figures released during this period by the Department of Labor consistently showed teenage blacks as the most significant structural unemployment problem for the nation. It is probably best left to others to unravel the message in this experience relative to the oft-heard "waning influence" of farmers and farm organizations and to the importance of individual and organizational leadership in solving urban and rural problems.

Another part of this book, and one that perhaps explains why Congressman Findley claims he will keep a copy near his desk, is a 140-page directory that lists organizations and firms that have an interest in food and agricultural policy, and gives other useful information such as founding dates, sources of funding, size of membership, and names of registered Washington lobbyists. The organizations and firms range alphabetically from Abbotts Dairies—a subsidiary of Fairmont Foods—to The Zuñi Indian Tribe of Zuñi, New Mexico.

Finally, a book like this raises many questions. One is whether or not large numbers of lobbyists may insulate policy makers from their constituents and contribute to the feeling that the government is unresponsive to the people. A second question relates to the view implicit in this book that the name of the game for policy makers is getting reelected: If true and if campaign finances are the key, can a major farm organization that only promises a declining number of votes expect to have an important role in shaping future farm and food policy? A third

---

and final question is whether growth in numbers of lobbyists leads to growth in staff of policy-making offices, or perhaps the reverse? Of course, it may not be simple causality but rather a simultaneous process spurred on by exogenous or endogenous influences. In either event, it creates a demand for trained staff, and that should create a demand for this book even without the usefulness that I would anticipate most classroom policy teachers would find for it.

Leo V. Mayer
Library of Congress
Washington, D.C.

Harl, Neil E. *Agricultural Law*. New York: Matthew Bender & Co., multivolume set, $60.00 per volume.

Will Rogers once said, "Everytime a lawyer writes something, he is not writing for posterity, he is writing so endless others of his craft can make a living out of trying to figure out what he said."

If Will Rogers had the opportunity to read Neil Harl's *Agricultural Law*, his opinion of the writing lawyer would change. First, Harl has written for posterity. In fact, this multivolume treatise is likely to be used as a legal reference well into the next century. Second, it is not difficult to "figure out" what Neil Harl says. His writing skill is well known and is truly exhibited in this monumental undertaking.

Harl's *Agricultural Law*, in the tradition of the legal treatise, is no mere book. It is a well-conceived and planned multivolume set. The original publication plans called for a ten-volume set, but at present fifteen volumes or more are contemplated. Each volume contains from 600 to 1,000 pages. About half of the set has been published, and the remainder will be released as volumes are completed over the next few months. As is typical for a legal treatise, the set will be updated continually (for an annual charge). The set cover is specifically designed to permit insertion of page revisions and "pocket part" supplements as necessary.

The treatise covers the entire gamut of agricultural law, ranging from business organizations to the Uniform Commercial Code. The early volumes include thorough coverage of the topics of civil liabilities, environmental law, labor law, income taxation of farmers, social security, federal unemployment tax, and estate planning. Topics in later volumes include business planning, government regulation of agriculture, state and local regulations, antitrust, commercial law, property law, insurance law, and agricultural cooperatives.

The set serves as an excellent research tool, in that each section is extensively annotated and footnoted. (In fact, many pages contain more footnotes than textual content.) Each section contains thorough discussions of statutes, both federal and state, case law, and administrative regulations pertaining to agriculture.

Matthew Bender and Company has a long and respected history of successful legal treatises in specialized fields. Harl's *Agricultural Law* is likely to be one of the most successful of these efforts. This work will appeal not only to the academician working in any of the fields of agricultural law but also to the legal practitioner who represents farm, ranch, or agribusiness clientele. The rural attorney will find that this treatise provides thorough coverage of a majority of the areas most likely to be confronted in practice.

The field of agricultural law has been expanding rapidly in recent years. Most agricultural economics departments have on staff one or more persons with legal training. Several law schools now offer one or more courses related to agricultural law. More practitioners recognize the special legal problems of agricultural clients, and a number of state and national bar associations have conducted continuing legal education programs relating to the legal problems of farm and rural people. This expansion has been accompanied (but at a slower rate) by some additional literature related to agricultural law. For example, *The Agricultural Law Journal* was launched in 1979 as a quarterly source of agricultural law information. A number of books are being developed for use in undergraduate and law school agricultural law courses and as potential research references. None of the books or treatises presently available or now underway will be as comprehensive as Harl's. Indeed, they are not designed to compete with but to complement this monumental effort.

In Will Rogers' remarks concerning the writings of lawyers, he added, "One level headed smart man could interpret every law there is." Neil Harl has come close to doing just that in *Agricultural Law*—at least for those areas of law impacting agriculture.

J. W. Looney
University of Arkansas

Paarlberg, Don. *Farm and Food Policy: Issues of the 1980s*. Lincoln and London: University of Nebraska Press, 1980, viii + 338 pp., $16.50.

The purpose of Paarlberg's book "is to identify the issues of farm and food policy . . . to report the known facts, to outline the alternatives, to foresee the probable alignment of various interested parties, to estimate the relative strength of the contending groups, and, if possible, to anticipate the outcome" (p. vii). Paarlberg's premise is that agriculture is losing its uniqueness and political power, which he measures in terms of the ability to control the farm policy "agenda." Modern technology and communications have eroded the distinctions between farmers and nonfarmers. Technology has reduced the number of farmers and consequently

their political clout. Ironically, the land grant colleges, which were established to serve agriculture's uniqueness, have been a major force in destroying that uniqueness.

Paarlberg believes the big commodity programs are in jeopardy because the public perceives food prices as being too high rather than too low and perceives commodity programs benefitting big farmers rather than small farmers. Because agriculture has lost political power, farmers will find it less risky to compete in the market than in the Congress.

After reviewing the old agenda of agricultural development and commodity programs in the first 60 pages, Paarlberg addresses the new agenda in the remaining 250 pages. Dating from the mid-1960s, the new agenda items have arisen from a diverse group of nonfarmers who had not previously been prominent in farm policy and who formed "the new zealous coalition with its food stamps, environmental programs, consumer issues, and rural development" (p. 63). Some of these eighteen new agenda issues, as reflected in the chapter titles, are "Price Control," "The Consumer Movement," "Domestic Food Programs," "Environmental Protection," "Prime Agricultural Land," "Energy and Food," "The Future of the Family Farm," "Is Zero Tolerance Tolerable," "The Great Thirst," "Agribusiness and the Restraint of Trade," and "International Food Aid."

Those who have heard Paarlberg speak will recognize the themes: "Agriculture Loses Its Uniqueness" (chap. 2) and "The New Agenda" (chap. 5). But, the book is not a collection of old or undelivered speeches or reminiscences. It is a sagacious evaluation of issues spiced with strategic suggestions. Paarlberg draws upon 500 references and four decades of experience as a Purdue University professor, White House special assistant, Director, Food for Peace, Assistant Secretary of Agriculture, and Earl Butz confidant.

His basic advice is to de-escalate the issues by searching out the facts, seek a common ground of understanding, and work out trade-offs. He concludes with this paragraph: "For a hundred years farmers held the policy initiative. They called the signals, moved the ball, and put points on the scoreboard. But sometime during the past fifteen years there was a turnover. Like it or not, farmers must now play defense. There is one thing worse than losing the ball; that is to lose the ball and think you still have it" (p. 308).

The book is exceptionally well-written in an easy-to-read, nontechnical manner. There are a few tables and charts but no diagrams. Almost every page contains a phrase one is tempted to cut out and paste on the wall. I call them "Paarlberg's Proverbs." Here is a sampling: "The worst thing to do is to listen to the rhetoric, which is likely to reflect circumstances that have become increasingly obsolete" (p. 12). "When the economist enters the world of policy, he must modify his assumption of frictionless and painless change or he too will feel the heat" (p. 31). "Experience shows that events are more influential in shaping farm policy than are previously stated positions" (p. 54).

There are three modest criticisms I might raise. First, more emphasis might have been given to agricultural technology and food demand prospects and their implications for policy. Second, Paarlberg probably overstates the ability of the market to solve the farm problem. He argues that overproduction is largely caused by market incentives. Neither market imperfections (externalities, economies of scale, uncertainty, immobilities), nor nonmarket phenomena (public agricultural research, agricultural fundamentalism, myopic politicians), play a significant role. Third, Paarlberg's arguments in support of food programs, regulation of agribusiness, environmental controls, etc., are not as persuasive as they might be. As a "traditionalist" (p. 9), his perspective and sympathy are closer to the old agenda than to the new one.

But, these weaknesses are more than offset by the book's strengths. I recommend it for undergraduate or graduate policy courses. I also recommend it to all those interested or involved in U.S. farm policy. In my opinion, the book will be quite influential and will become a classic.

Penson, John B., Jr., and David A. Lins. ***Agricultural Finance—An Introduction to Micro and Macro Concepts.*** **Englewood Cliffs, N.J.: Prentice-Hall, 1980, 546 pp., $18.95.**

Agricultural finance owes its identity as a sub-discipline of agricultural economics largely to Murray's textbook, first published in 1941, and revised six times by other authors over the past forty years. In recent years several world events, particularly the unchecked price inflation of the 1970s, have worked together to create demand for textbooks which can deal with a variety of problems in the financing of agriculture (farming). The text by Penson and Lins is, in some ways, the most comprehensive treatment to date of this still emerging sub-discipline. It may be viewed as another step in the advance of agricultural finance as something more than an offshoot (or subset) of farm business management.

The book is organized into four parts: (*a*) an introductory chapter on the scope of agricultural finance, (*b*) eleven chapters (278 pages) on farm financial management, (*c*) six macrofinance chapters (139 pages), and (*d*) five chapters (98 pages) on financial intermediaries serving agriculture. The organization, other than the additional macro chapters, is essentially similar to that found in other agricultural finance texts. However, in several chapters, the degree of abstractness, and perhaps the detail, seems to be beyond what students can

comprehend adequately in an introductory agricultural finance course. This is especially true of some portions of the chapters (4 and 5) on firm growth and capital investment. Mathematical notation in chapter 5 and in the chapter on the cost of capital (8) is unorthodox at best. It could be confusing to students, even those who have learned the standard notation of the mathematics of finance.

The two "macro chapters," on a national financial accounting system (13 and 14) and the following chapter on capital intensification and utilization in U.S. agriculture, demonstrate the authors' finest skills. Their firm grasp of this area of agriculture is summarized at its best. In contrast, the chapter on explaining aggregate investment and financing behavior (16) somehow just does not click. It tends to betray the objectivity and clarity of expression achieved in chapters 13–15. Perhaps this is due to the subjective, hypothetical nature of the chapter's content—a point the authors themselves make on its opening page.

Chapters on monetary and fiscal instruments and policy (17 and 18) are more-or-less tacked on to the other "macro chapters." The policy instrument chapter (17) could be more appropriately grouped with those on financial intermediaries (part four). The policy action chapter (18), as the authors admit, is devoted almost entirely to manipulations of parameters within the standard Keynesian model. What purpose does this serve as a separate presentation in an introductory or intermediate-level agricultural finance text?

To the authors' credit, the concise treatment of risk in capital investments is handled separately in chapters 6 and 7. In an introductory course, this makes it easier for instructors who elect to scan such material. Those who elect to cover such material in more depth in an intermediate-level course may wish to use such separate chapters for review purposes.

Chapters on legal considerations, business organization types, income tax management, and estate planning (9–12) also seem to be more complex than students enrolled in an introductory course should be required to assimilate. This complexity, or attention to detail, is woven throughout the narrative, thus largely precluding class assignments of only portions of a chapter. For example, the income tax chapter tends to focus on describing the current IRS code and attendant forms rather than outlining and explaining the basics of farm income tax management.

Perhaps the authors are most open to criticism in their treatment of capital investment and capital costs (chapters 5 and 8). However, the deficiencies in these chapters are not uncommon in the agricultural finance literature. If one demands an accurate, clear, and more complete treatment of these topics he (she) must turn to a text on capital investment analysis. A complete treatment of the topics obviously is not possible in only two chapters. What is expected, though, is a fairly clear treatment. But clarity is not found in several places; even accuracy is lacking in parts of the capital cost chapter.

When discussing add-on loans, the authors incorrectly explain how to partition each period's loan payment into a part for interest and the remaining part for principal. Constant interest payments are in fact not made with an add-on loan. The pure discount method (the only case they present) usually is modified so the borrower can obtain an original principal amount equal to that obtained with an add-on loan. Nominal interest rates (APR's), shown in table 8.4, are substantially overestimated for both add-on and discount methods when there are more than two loan payments each year. The authors could have cleared up some of these mistakes by a fairly brief explanation of the "Rule of 78's" and proceeded to show how the rule is applied for their installment loan examples. In general, more attention to loan cost terminology is needed throughout chapter 8.

The critical comments of this review must be seen in the light of an absolute set of norms. Ideal chapters are easy for finance instructors to demand but extremely difficult to deliver, especially in an original edition. My overall evaluation is that Penson and Lins have presented us with a book which should prove to be functional in several ways: (*a*) as an intermediate level text, (*b*) as a reference source for an introductory course, and (*c*) as a review source for beginning graduate students majoring in agricultural finance.

Garnett Bradford
University of Kentucky

Rausser, Gordon C., and Eithan Hochman. *Dynamic Agricultural Systems: Economic Prediction and Control.* New York: Elsevier North-Holland, 1979, 364 pp. (volume 3 in a series of volumes in Dynamic Economics: Theory and Applications).

This is an important book with serious flaws. It is important because of the dynamic and risky features of agricultural systems. The returns from more analyses of the type referred to appear to be great, and relatively few agricultural economists are equipped to utilize these tools. Many would find it useful to have an accessible exposition and clear demonstration of the use of these tools.

Unfortunately, this volume is flawed in both concept and execution. It seems that the authors and editor could not decide whether to produce a textbook, a research monograph, or a collection of prior works of the authors. A successful textbook would require a more careful exposition of the techniques and some practice exercises. A successful research monograph would have more original material and more detailed proofs. A collection of previous works would usually compile a greater volume of works. In execution, fundamental errors of English grammar are sufficiently numerous to be

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

American Agricultural Economics Association

President/Luther G. Tweeten, Oklahoma State University
President-Elect/G. Edward Schuh, University of Minnesota
Secretary-Treasurer/John C. Redman, University of Kentucky
Past-President/Richard A. King, North Carolina State University

Directors

Thomas G. Brown, University of Missouri
Carleton C. Dennis, Agway, Inc
Neil E. Harl, Iowa State University
Richard G. Heifner, AMS USDA
John A. Hopkin, Texas A&M University
William E. Martin, University of Arizona

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $ 0.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.

In this issue: Proceedings papers from the 1980 AAEA-AEA joint meeting

AAEA Annual Meeting
Clemson University
Clemson, South Carolina
26–29 July 1981

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Ames, Iowa, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, James P. Houck, Department of Agricultural and Applied Economics, 332 Classroom Office Bldg., University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Ronald A. Schrimper, Department of Economics and Business, P. O. Box 5368, North Carolina State University, Raleigh, NC 27650

The Effects of Changing Input Costs on Food Prices

R. McFall Lamm and Paul C. Westcott

The relationships between changes in food sector input costs and retail food prices are examined. Results indicate that increases in factor prices pass quickly to consumers, within two quarters for most foods. In addition, rising farm-level prices and substantial increases in nonfarm resource prices appear to explain why food prices rose more rapidly than nonfood prices in the 1970s. The analysis is based on a twenty-equation econometric model of the food-price determination process, specified following Popkin's "stage of processing" approach. Causality and validation test statistics for the model are presented.

Key words: food prices, forecasting model, simultaneous equation system, stage of processing.

During the 1970s, retail food prices increased an average of 8% per year. This was significantly greater than the 6.8% annual rise in nonfood prices and represented a reversal of the pattern in the 1950s and 1960s when food prices increased at a lower rate than nonfood prices. Although money market developments were largely responsible for the rising level of food prices during the 1970s, few satisfactory explanations have been offered concerning why food prices rose faster than nonfood prices.

The purpose of this paper is to consider this issue by examining the relationships between changes in factor prices and changes in retail food prices. A major concern is the impact on consumers of changes in raw foodstuffs prices, as well as the impact on consumers of changes in the cost of other resources used in food processing and distribution. The analysis is based on an extension of Popkin's "stage of processing" model, which provides a general representation of price determination processes. A small, quarterly, econometric model consisting of twenty linear equations serves as a foundation for the study.

The markup model proposed by Popkin requires that prices be written by "stage of processing" as functions of current and lagged resource prices as well as excess demand variables. This approach contrasts with that used for standard markup models and other price determination models (see Gardner, Heien, Maccini, and Phelps, for example) in that there is a greater emphasis on utilizing the appropriate industry price variables than is typically the case. Popkin's principal argument, and the one adopted in this paper, is that there are many theories of price determination, none of which can be demonstrated superior to the others. Consequently, general price equations embodying the central theses of many different theories may serve as empirical approximations.

The Model

It is assumed that retail food prices are determined by the general markup process

$$(1)\quad p_{it} = \phi_i[E_{t-1}(p_{it}); \mathbf{p}_{it}, \ldots, \mathbf{p}_{i,t-n}; \mathbf{r}_t, \ldots, \mathbf{r}_{t-m}] \qquad i = 1, \ldots, I;\ t = 1, \ldots, T,$$

where $E_{t-1}(\ldots)$ is an operator generating the expected value of the operand in period t conditional on information available in $t-1$, $\mathbf{p}_i$ is a vector of the prices of goods which are substitutes or complements for the ith good ($p_i \notin \mathbf{p}_i$), $\mathbf{r}$ is a vector of input prices, and the variables n and m denote maximum lag lengths. In

R. McFall Lamm, Jr., is section leader, and Paul C. Westcott is an economist with the Food Price Analysis Section, Economics and Statistics Service, U.S. Department of Agriculture.

The authors gratefully acknowledge the helpful comments of L. Salathe, J. Craven, and the *Journal* referees. Opinions presented do not necessarily reflect those of the U.S. Department of Agriculture.

general, the signs of the $\partial p_{it}/\partial r_{js}$ $s \leq t$ are expected to be positive—increases in resource prices are passed through to output markets. The signs of $\partial p_{it}/\partial E_{t-1}(p_{it})$ are indeterminant and depend on the nature of market power in the industry and the extent to which consumers are able to substitute for the ith food. Similarly, the signs of $\partial p_{it}/\partial p_{js}$ $s \leq t$ are indeterminant, depending on whether the jth good is a complement or a substitute.

An interesting aspect of equation (1) is its simultaneous structure. Most markup models have excluded the prices of close substitutes and complements, relying instead on various demand pressure variables such as overtime hours and excess capacity in the markets being analyzed. Simultaneity in consumption is an important aspect of food price determination, however. When retail beef prices rise significantly, there is usually a demand pull effect on pork and poultry prices, for example. This is an important part of the food-price-determination causal chain.

Another important feature of the process specified in equation (1) is the nature of the relationship between output and input prices. Different output prices are jointly determined by expectations, current input prices, and lagged output prices. But the causal path between resource prices and output prices is assumed to be unidirectional—resource prices determine output prices. In most manufacturing industries where imperfect competition prevails, this assumption would be acceptable. However, the processing and distributing functions for some foods are carried out in competitive markets. Hence, this assumption may be questionable.[1] Farm-level commodity prices and retail food prices may be determined simultaneously. Alternatively, retail food price changes may cause farm-level price changes if consumer demand variables such as tastes, income, and expectations dominate the retail food price determination process.[2] Consequently, it is necessary to view the assumption that farm-level prices cause retail food prices as a conjectural hypothesis to be tested.

Empirical Implementation and Estimation Results

To estimate the model, equation (1) is assumed linear, with the included variables representing candidates that might appear in structural equations for each of fifteen major BLS food groups considered in the study. Although several processing stages are required to transform raw foodstuffs into finished consumer foods, the farm-to-retail processing and distribution function is viewed essentially as one stage. This is a necesssary simplification, given data limitations and the problem of separating vertically integrated firms by processing stage.

Dependent price variables are expressed as quarterly percent changes, as are all other variables except seasonal dummies and a time trend variable. Retail food prices are represented by the appropriate consumer price indexes (CPIs); wage rates come from the BLS employment and earning series; farm-level prices for foodstuffs come from the "prices received by farmers" series maintained by the U.S. Department of Agriculture (USDA); and imported food prices and prices for other inputs used in food processing and distributing (energy, paper, glass containers) are represented by the appropriate producer price indexes (PPIs). Each series is obtained by averaging the appropriate monthly data. Estimation is based on percent changes from the second quarter of 1968 through the fourth quarter of 1977. In addition, data from the first quarter in 1978 through the last quarter in 1979 are retained for validation purposes.

Each of the fifteen retail food price equations included in the model was developed deductively—the dependent price variable was first selected and the appropriate wages, farm-level prices, and other resource prices were then included. In addition, because of the importance of seasonal effects in the food price determination process (prices are generally lower at harvest, for example), quarterly seasonal dummies were added. Each equation was then estimated using ordinary least squares (OLS). Variables not contributing significantly to explanatory power were deleted from each equation following Theil's (1971) explanatory set reduction strategy. Al-

[1] Parker and Conner indicate that the total social loss due to monopoly in food manufacturing was on the order of \$10–\$12 billion in 1975, while Marion et al. estimate that monopoly overcharges in the food retailing industry may be as high as 6.8% of total food sales in some metropolitan areas. But in many food-manufacturing industries and in numerous urban food markets, 4-firm concentration ratios are less than 0.4—the point typically used to distinguish effective from imperfect competition.

[2] For example, an increase in consumer tastes for a group of foods or a rise in income would lead to an increase in retail food prices. Farm foodstuffs prices would increase as a consequence. In this way, higher retail food prices would "cause" higher farm-level prices.

ternative price expectation formation processes also were evaluated in this way, with a simple first-order autoregressive process generally found to be acceptable. These specification experiments were viewed as necessary steps because the model is not based explicitly on one theory of behavior and because forecasting accuracy is a major design goal.

Although the CPI for food consumed at home is a weighted sum of the fifteen food price indexes included in the study, the estimation of an aggregation equation is necessary to obtain changes in "grocery store" prices from the model. Adding another behavioral equation explaining the determination of changes in away-from-home food prices (at restaurants, cafeterias, and fast food establishments), and adding a second aggregation equation relating changes in the CPI for all food to changes in the CPIs for food consumed at home and away from home, gives estimates of changes in the "all food" CPI. To allow interaction between changes in food sector prices and those in the rest of the economy, two additional equations were added: a Phillips curve relating nonfood price change to changes in unemployment and other variables and an aggregation relation expressing changes in the CPI for all items as a linear combination of changes in the food and nonfood CPIs. The result is a simultaneous model consisting of seventeen behavioral relations and three aggregation equations.[3]

Following preliminary estimation by OLS, the complete model was estimated using three-stage least squares under the assumption that stochastic errors were correlated across equations.[4] Estimation results are presented in table 1. Variable definitions are given in table 2. In general, the statistical fit of the model is excellent—virtually all variables are highly significant, the signs on all input prices are positive, and the estimated coefficients appear to be appropriate in magnitude.

One important result reflected in the estimates is the low order of the lags in the behavioral equations—the maximum lag which appears in any equation is one quarter. Indications are that increases in input prices, changes in expectations, and demand shifts all impact almost immediately on retail food prices. This contrasts with results typically presented for nonfood markup models, which often exhibit complex lag patterns, and is probably a consequence of the perishability of food.

Other characteristics of the model include: (*a*) the limitation of simultaneity, principally to high protein foods—current endogenous variables are included on the right-hand side only for meats, poultry, and fish (and aggregation relations); (*b*) an important role for expectation formation—lagged own prices enter seven behavioral equations; and (*c*) an important role for seasonality—binary seasonal variables are included in eight behavioral equations. These model characteristics derive largely as a consequence of the statistical criteria used in specification.

Causality Tests

An important assumption underlying estimation is that farm-level prices cause retail food prices, implying that farm foodstuffs prices are the appropriate right-hand-side variables. If this is not the case, then the model is invalid because causality is postulated as unidirectional from farm to retail level prices. This assumption is tested explicitly following a procedure suggested by Mehra for implementing Sims' causality test. The necessary steps include (*a*) filtering the retail and farm-level-price time series to remove autocorrelation, and (*b*) regressing each filtered series on the current value, four future values, and eight lagged values of the other series, as well as on seasonal dummies and a time trend. F-tests on each regression are then performed to determine whether the coefficients attached to future values are significantly different from zero. Under the null hypothesis that the dependent variable does not cause the independent variable in each regression, the coefficients of future values will jointly be zero.

Table 3 presents F-statistics of the null hypothesis that farm-level prices do not cause retail food prices, and that retail food prices do not cause farm-level prices. In addition, parameter values for the second order filters used for each price series are also presented. The results imply that in seven out of eleven

[3] The relationship between percent changes in the CPIs for all items, food, and food at home and percent changes in the components making up these aggregates is not an exact identity, although the relationship between the levels of these indexes is exact. This is because the transformation from levels to percent changes is nonlinear.

[4] Predicated values for endogenous variables in the second stage of estimation converged to their actual values, so actual endogenous values were used in the third stage.

[a] Estimates are based on quarterly data from 1968-2 through 1977-4.
[b] Standard errors are presented in parentheses.

cases the hypothesis that farm foodstuffs prices do not cause retail food prices can be rejected with 99% confidence—the critical F-value with (4, 15) degrees of freedom is 4.89. In contrast, in only one out of eleven cases can the hypothesis that retail prices do not cause farm foodstuffs prices be rejected. The basic implication is that causality is unidirectional from farm to retail prices for all foods considered in the study, except between the cereals and bakery products CPI and wheat prices (which are determined to be jointly causal) and between retail and farm-level prices for fresh fruits and vegetables (for which no causal relationship is found). This finding is generally consistent with Heien's results using monthly data and it supports the use of a markup pricing model representation of the food price determination process.

Validation

Any econometric model that is a valid representation of the system it is designed to emulate must be able to explain behavior over the

estimation period and over a data set not included in estimation. The typical approach in time-series analysis is to reserve the most recent data available historically for a "beyond sample" validation—usually two to three years for a quarterly model—while using the bulk of the information set for estimation and a "within sample" validation. Simulated deterministic time paths for endogenous variables are generated using the model and compared with actual system time paths for consistency. This is the approach followed here.

Table 4 presents summary validation statistics for a comparison of simulated deterministic time paths with actual system paths. The simulated time paths are produced by using actual lagged endogenous values in the first period solution, and then using generated lagged endogenous values in successive solutions, allowing a complete dynamic response. Actual exogenous values are used for all solutions. The "within sample" validation covers the estimation period from the second quarter of 1968 to the fourth quarter of 1977, while the "beyond sample" validation covers the eight quarters of 1978 and 1979. Mean absolute percentage errors (MAE) and Theil (1966) inequality coefficients are presented for each CPI category.

The results indicate that the model performs extremely well, both for the "within sample" validation and the "beyond sample" validation. The MAEs are small and all inequality coefficients are substantially less than unity for the within sample validation. The MAEs and inequality coefficients for the beyond sample validation indicate a less satisfying performance, but nonetheless are supportive. The largest MAEs occur for fresh fruit and fresh vegetables—foods particularly sensitive to labor disputes and transportation problems. The largest inequality coefficients occur for sugar and sweets, nonalcoholic beverages, and processed fruits and vegetables—markets characterized by a high degree of nonprice competition. The model does not include an advertising cost measure that might improve the performance of the equations for these foods.

Table 5 presents quarterly forecasts for the beyond sample validation. Predicted changes in the three major food CPIs considered in the study are given, based on actual exogenous data and generated endogenous data. These results illustrate on a quarter-by-quarter basis how well the model performs, over a period not used in estimation, in the prediction of three food price aggregates which are of most interest to policy makers.[5]

An even more stringent validation is possible if the exogenous values of the model are also forecast. This represents a complete test of the model as a forecasting system, and allows a direct comparison with food price forecasts generated by other models. Two procedures are used to predict the values of exogenous variables in this study: (*a*) all exogenous values are forecast using autoregressions of

[5] The validation statistics presented here are superior to similar data for a food price-forecasting model developed by Barr and Gale.

Table 3. *F*-Statistics and Filters for Tests of Causality Hypotheses

current exogenous variables on lagged exogenous variables (twelve quarters of lags for cattle, hog, wheat, and soybean oil prices, and four quarters of lags for all other exogenous variables), a time trend, and seasonal dummies; and (*b*) farm-level prices are forecast using patterns of change implied by the appropriate futures market prices, with other exogenous variables forecast using autoregression. In this latter procedure, futures prices from the last business day in December are used to obtain quarterly forecasts for the following year by interpolation and averaging monthly contract values. Futures prices for cattle, hogs, broilers, and eggs are from contracts traded on the Chicago Mercantile Exchange; futures prices for wheat and soybean oil are from the Chicago Board of Trade; and futures prices for coffee and sugar are obtained from the New York Coffee and Sugar Exchange.

Table 6 presents actual changes in the CPI for food, forecast changes in the CPI for food based on the two procedures just described, and USDA Outlook Conference forecasts of the CPI for food over the eight quarters in 1978 and 1979.[6] Indications are again that the model performs well, particularly with respect to the USDA forecasts—the mean absolute error for the model using either exogenous variable forecasting procedure is about half the error in the USDA forecasts.

Implications

Proceeding under the assumption that the model is well specified and a valid representation, as the evidence would suggest, it is important to review the full implications of the structural equations presented in table 1. In this regard, since the model is linear, it becomes a simple matter to derive the reduced form of the model from the structure, and to generate the appropriate dynamic system multipliers from the reduced form. This allows a more complete synthesis of the information contained in the structural parameters, provides yet another means for validating the model, and serves to delineate some of the model's weaknesses.

Table 7 gives Goldberger impact and total multipliers for ten selected exogenous variables—three farm-level prices, three producer price indexes, and four wage rates—with respect to all endogenous variables except the nonfood CPI. Each impact multiplier gives the effect of a 1.0% increase in the exogenous

[6] The USDA Outlook Conference is generally held each November to brief farm organizations, the press, food processors, and food distributors on forecasts for the coming year.

Table 6. Model Forecasts of Changes in the Consumer Price Index for Food, 1978-1 through 1979-4

		Forecast Change with Exogenous Variables Predicted by		
Quarter	Actual Change	Auto-regression	Auto-regression and Futures Prices	USDA Outlook Conference Forecast

variable on the appropriate endogenous variable in the current period, while the total multipliers represent the effect of a 1.0% increase when all lagged adjustments are considered. Each of the multipliers is generally of the expected sign and magnitude, with the most important summary information contained in the multipliers on the food at home CPI, the food CPI, and the total CPI.

On the basis of the impact multipliers, food-at-home prices are affected most by higher wages at food and grocery stores. A 1.0% increase in retail wages in the current quarter leads to an immediate increase in food-at-home prices of more than 0.4% and a rise in total food prices of slightly more than 0.3%. The same increase also pushes up the total CPI by .075%—the largest impact of any food sector input price on the total CPI. Increases in meat-packing plant wages and in nonagricultural establishment wages (a proxy for food-processing wages) also have large immediate impacts. These findings are consistent with USDA data attributing about one-third of the cost of food to labor.

Changes in farm-level prices for cattle, hogs, and broilers also have significant immediate impacts on retail food prices and the CPI for all items. A 1.0% rise in cattle prices causes a .285% increase in the CPI for beef and veal, a .038% rise in the CPI for food, and a .009% increase in the CPI for all items. Upward movements in hog and broiler prices have similar impacts, although of lesser magnitudes. Changes in cattle, hog, and broiler prices also have a positive impact on the CPIs for other meats and fish. There is no immediate impact on restaurant and cafeteria prices from current increases in farm-level meat prices, largely because of contracting by chains and delays in the menu pricing process. The interim multipliers for these variables in the two subsequent quarters are substantial, however.[7]

The impact of increases in other resource prices is dominated by energy. A 1.0% rise in the PPI for energy, which reflects both power and transportation cost increases, leads to a .261% increase in beef prices, a .068% increase in pork prices, and a .075% rise in prices for other meats. The same increase also pushes up fish prices .165%, and processed fruits and vegetable prices by .362%. The immediate impact of a 1.0% increase in energy prices on the CPI for food is a .055% increase. After one quarter, the interim multipliers for a 1.0% increase in energy prices are large for some foods because of the lag before higher prices are passed through to retail. A 1.0% increase in energy prices this quarter leads to a .032% rise in the CPI for food next quarter, and a .010% increase two quarters ahead. Three quarters ahead and beyond, the impact of a 1.0% increase in energy prices in the present quarter is virtually zero.

The small size of the energy interim multipliers beyond two quarters ahead is a general characteristic of all interim multipliers in the model. Changes in input prices for the food industry have their greatest effect on retail food prices in the current quarter and one quarter ahead, with a smaller impact two quarters ahead and insignificant impacts three and more quarters ahead. This multiplier pattern serves to distinguish the food sector from other sectors in the economy that generally exhibit more complex lag structures and larger interim multipliers in later quarters. This finding has important implications with respect to public policy implementation at the farm level. Indications are that policies that affect farm-level foodstuffs prices have an effect on retail food prices almost immediately. Similarly, changes in wages and nonlabor resource prices are quickly passed through to the retail level.

Virtually all total multipliers are fairly small multiples of the impact multipliers, additional evidence of the short time lag before increasing resource prices are passed through to consumers. The magnitudes of the total multipliers further illustrate the importance of labor, energy, and packaging materials as important determinants of retail food prices. One implication of this result is that the role of changing input prices is a crucial aspect of the recent food price inflation. This role is often overlooked in the public dialogue on the causes of higher retail food prices.

Conclusion

This paper has reviewed the nature of the relationships between changes in food sector input prices and retail food prices based on a small econometric model. The model is a generalization of Popkin's "stage of processing" approach and includes all of the major inputs used in domestic food production. The basic findings are that (*a*) the lag structure of the food industry is relatively simple, with most of

[7] Interim multipliers are not presented in the text. They are available from the authors in a statistical appendix which also includes a listing of the data used in the analysis.

the impact of changing resource prices being passed through to the retail level within two quarters; and (*b*) changes in nonfarm resource prices are important, even dominant, in the food price determination process. With respect to the lag structure, the results presented here confirm findings by Barr and Gale indicating a fairly simple lag structure for the food industry. In addition, the finding that changes in farm-level prices are passed through quickly to retail, especially for fresh foods, confirms results obtained by Heien and Lamm using monthly models. With respect to nonfarm resource prices, the model is consistent with USDA estimates of the relative contributions of various inputs to retail food price determination.

The identification of the most significant determinants of retail food prices provides a response to the question of why food prices increased more rapidly than nonfood prices in the 1970s. From 1970 to 1979, the price of farm commodities used in food rose 9.1% per year; all wage rates represented in the model increased more than 7.1%; and the energy PPI increased 15.8%. These increases, when passed through to consumers, led to the 8.0% annual rise in the CPI for food over the period. This contrasts significantly with the 6.8% increase in nonfood prices. On this basis, it is apparent that not only were rising farm-level prices an important cause of higher relative food prices in the 1970s, but increases in nonfarm resource prices were important as well.

Commodity Price Forecasting with Large-Scale Econometric Models and the Futures Market

Richard E. Just and Gordon C. Rausser

This paper compares the accuracy of major commercial price forecasts for corn, wheat, soybeans, soybean oil, soybean meal, cotton, live cattle, and hogs. The price-forecasting information in futures prices is evaluated by comparison. The results among commercial forecasters are mixed, but futures prices perform relatively better on average although not universally so. These results have important implications for operational risk management.

Key words: futures prices, price forecasting.

Commercial forecasts of spot prices in agricultural commodity markets have been available since 1976. These forecasts are produced quarterly, refer to specific cash markets, and cover a number of commodities. The firms that generate and sell these forecasts, largely to agribusiness companies, include Chase Econometrics, Doanes Agricultural Service, Data Resources, Inc. (DRI), and Wharton Econometric Forecasting Associates. The U.S. Department of Agriculture (USDA) also develops such forecasts for internal use. Most of these forecasts are based upon large-scale, U.S. agricultural sector models which specify formal links among individual commodities. The purpose of this paper is to compare and evaluate the price-forecasting experience and accuracy of the commercial vendors that produce point forecasts.

The questions addressed include the following. What is the comparative and absolute accuracy of the various vendors? Does the comparative accuracy of different models depend upon the forecast horizon—for example, is one model more accurate for, say, a one-quarter forecast and another more accurate for a two-quarter-or-longer term forecast? Is the relative and absolute forecast accuracy commodity dependent? What types of errors tend to be made by various firms, and how do these relate to a user's selection of forecast to purchase?

The commodities examined include corn, wheat, soybeans, soybean oil, soybean meal, cotton, live cattle, and hogs. One-quarter through four-quarter forecast horizons are investigated. Accuracy is evaluated by computing two statistical measures of equality—root mean squared error and root mean squared percentage error—of the forecasts of average quarterly cash market prices over the period 1976–1978.

The price-forecasting information contained in futures market prices is also evaluated. Some of the literature on futures markets questions the quality of futures prices as forecasts (Working, Tomek and Gray, Labys and Granger). Working (p. 49) states that "it is not true that futures prices afford forecasts of price change in the sense in which one speaks of the price forecasts of a market analyst" but, however, "neither is it true that futures prices provide no sort of forecast of price change." In addition, much of the recent conceptual work on futures markets views futures prices as rationally based expectations (Danthine; Peck;

Richard E. Just is a professor and Gordon C. Rausser is a professor and chairman of the Department of Agricultural and Resource Economics, University of California, Berkeley. Note that senior authorship is not assigned.

Giannini Foundation Paper No. 594 (reprint identification only).

The authors gratefully express their appreciation for the timely computational assistance and suggestions of Efraim Gutkind, Joseph Yassour, L. Joe Moffitt, and Elaine Borkon. Furthermore, this paper would not have been possible without the helpful assistance of Ray Daniels of Chase Econometrics; Allen Dever of Doanes Agricultural Service, Inc.; Bruce Scherr and Bill Connors of Data Resources, Inc.; Dean Chen of Wharton Econometric Forecasting Associates; and Ed Overton and Abner Womack of the U.S. Department of Agriculture.

Feder, Just, Schmitz; Holthausen; Turnovsky; Anderson and Danthine). Some recent empirical evidence also strongly suggests that futures prices play an important role in the formation of producer price expectations (Peck, Gardner).

In an earlier paper (Rausser and Just), a simple analogy was established between forecasting prices from futures markets and forecasting prices with econometric models. Especially in the case of futures markets, the "aggregate market participant processes" must perform much the same role as an econometric model. Participants must form expectations or forecasts of important exogenous influences—e.g., planning intentions, yields, consumption, export demand, etc.—and transmit this information into a futures price. In addition to random noise, errors can be made in formulating forecasts of the exogenous information or in the transmission of this information into an observed futures price. In the latter context, errors in futures markets arise from uninformed market participants, risk aversion, irrational market participants, imperfect capital markets, and alternative transaction and information costs. These errors in econometric models arise from omitted variables, inappropriate functional forms, measurement errors, aggregation, and the like. With this analogy in mind, futures markets can serve as a basis of comparison for price-forecasting errors emanating from econometric models. Potentially, it is possible for the large-scale econometric models examined in this paper to outperform futures market prices as price forecasters.

In the above setting, this paper addresses the question of whether futures markets are more or less accurate than the large-scale, econometrically based forecasts. The response to this question has some direct implications for future conceptual work as well as operational risk management frameworks of companies that currently purchase econometric forecasts. These implications hold regardless of whether futures market prices are used by commercial vendors to alter their econometric price forecasts (in an ad hoc fashion) or whether traders employ the econometric model price forecasts in determining their positions in futures markets.

The Commercial Forecasts

All four commercial firms considered in this study began making commercial point forecasts of agricultural prices during the latter half of 1976. The frequency and horizon of the respective forecasts thereafter are indicated in table 1 for the eight major agricultural commodities examined by our analysis. In each case, firms made forecasts on a somewhat irregular basis initially but then settled down to a regular pattern in 1977. Since April 1977, DRI's forecasts have been monthly and cover forecast horizons from one to eight quarters. Since June 1977 (October 1977, for soybean oil and meal), Chase has made forecasts with one to eight-quarter horizons on a bimonthly basis. Wharton has forecasted from one to six quarters ahead nearly every month since April 1977. Doanes has made forecasts less frequently (on a quarterly basis) for six of the eight commodities and has forecasted with a horizon of only two, three, or four quarters. The USDA also has been operating on a quarterly basis throughout this period with forecast horizons of one, two, or three quarters.

The Futures Market Price As a Standard of Comparison

For some commodities, several futures markets exist, while for others only a single futures market exists. Since our focus does not address a comparison of futures markets, we narrow the alternative price forecast possibilities by using the Chicago Board of Trade prices for wheat, corn, soybeans, soybean meal, and soybean oil; the New York Cotton Exchange for cotton; and the Chicago Mercantile Exchange for hogs and live cattle.

Given the specified markets and the desire to generate price forecasts, an issue arises as to the appropriate filter of futures market prices to use as a predictor of spot price for the contract month. One approach to this problem is to solve for an optimal filter of futures market prices in current months in predicting spot prices in contract months. The approach taken here, however, is more intuitive and is designed to serve as a standard of comparison with commercial forecasts for which easy access is available. Moreover, to make the comparison fair for the econometric forecasters, the futures market price forecaster should be constructed from information available at about the same time of the month as used by the econometric firms. Most econometric firms collect information about the second week of the month for formulation of forecasts produced near the end of the month. Thus, for

Note: Figures in parentheses give 1978 information where it differs from 1977. Where figures appear only in parentheses, no forecast was made in 1977.

[a] Reports a forecast also for cotton price made in April 1976, but this forecast was excluded from the analysis because other firms were not operating in comparable time periods.

[b] Note that the USDA does not forecast cotton price.

[c] Blanks indicate no forecasts were made.

[d] Wheat price was forecasted only two quarters ahead by USDA in August 1977.

the purposes of this paper, we selected as the forecast the average of daily futures market closing prices for the second week of the month. This information is readily available to every decision maker; yet, it does not embody more exogenous information than is supposedly available to the econometric firms. It should be kept in mind, however, that decision makers actually may have access to better information by using futures prices generated later in the month when econometric forecasts actually become available.

Due to the quarterly temporal dimension of the econometric forecasts, a further issue arises as to which contract month for a futures market should be used to represent the forecast horizon. That is, should an econometric forecast for live cattle price in the second quarter of, say, 1980 be compared with the corresponding April or June futures contract price? In some quarters, only one contract exists so no choice is available. In other quarters, however, two or three contracts may be applicable. For the purposes of this study, the midmonth in each quarter is used when available. If a contract does not exist for the midmonth, then the contract for the latter month is used since the prices of these contracts would tend to use more of the information that would affect average quarterly spot market price than the first-month contract. Of course, the first-month contract is used if no other contract exists in the quarter. The futures contracts used are as follows. May is used for the first quarter except for livestock, where February is used. For the second quarter, June is used for livestock and May for all other commodities. For the third quarter, August is used for livestock and soybean derivatives; July for cotton; and September for all others. Finally, for the fourth quarter, November is used for soybeans and December for all others.

The Basis of Comparison

Two sets of comparisons were examined. Due to space limitations, only the first set of comparisons based on the best forecast available from each source by month for the period from December 1976 through December 1978 will be reported. The forecasts prior to December 1975 are excluded from the analysis because not all four firms began forecasting on a commercial basis until that time. The use of the term, "best available" forecast, implies that each firm's forecast in each month is taken to be its latest published forecast. For example, if Doanes makes a forecast in April 1977 and does not make another forecast until August 1977, then the April forecast is used as Doanes' best available forecast in the months of May, June, and July. For customers who need price forecasts on a regular basis for decision-making purposes, it seems that this type of comparison is more meaningful than simply comparing the forecasts only over the set of months in which they actually are made. Admittedly, however, this comparison favors DRI, which revises its forecasts monthly, relative to Doanes, which revises its forecasts only quarterly.

To determine the extent of this bias and to develop more information about the actual forecasting ability of each firm, as opposed to the futures market, a second set of comparisons also was constructed using only those months in which the major commercial econometric firms (excluding Doanes and USDA) actually revised their forecasts. To develop strictly fair comparisons for Doanes and USDA, additional pairwise comparisons were made between DRI and Doanes and between DRI and USDA using only those months in which both made new forecasts. These results are available on request but are too lengthy to present here.

The comparisons employ two statistical measures of quality—root mean squared error and root mean squared percentage error. Due to practical limitations on computation and the desire to simplify the reporting of results, other measures of quality are not investigated here. Moreover, other types of measures—such as mean absolute deviation and Theil U coefficients—generally lead to the same rankings of forecasts for the forecasting problem considered here (St. George et al.).

The econometric firms do not all forecast the same actual price series.[1] Thus, problems

[1] The price series forecasted by the econometric firms considered in this study are as follows: wheat—Chase and Wharton, No. 1 Hard Red Winter wheat, Kansas City ($ per bu.); Doanes, average price received by farmers, United States ($ per bu.); DRI, average of Kansas City, Minneapolis, Portland, and St. Louis prices ($ per bu.); corn—Chase, DRI, and Wharton, No. 2 Yellow corn, Chicago ($ per bu.); Doanes, average price received by farmers, United States ($ per bu.); cotton—Chase, Doanes, and Wharton, average price received by farmers, United States (¢ per lb.); DRI, upland cotton lint price, USDA (¢ per lb.); soybeans—Chase, DRI, and Wharton, No. 1 Yellow soybean price, Chicago ($ per bu.); Doanes, average price received by farmers, United States ($ per bu.); soybean meal—Chase, DRI, and Wharton, bulk, 44% protein price, Decatur ($ per ton); soybean oil—Chase, DRI, and Wharton, crude tank FOB price, Decatur (¢ per

arise regarding comparability due to transportation costs and other factors which cause a divergence of prices in different markets. Also, in using futures market prices as forecasts of spot market prices, one must consider delivery costs. To account for the effect of these factors in the commercial forecasts, each econometric forecast is compared to the actual respective price being forecasted. In order to avoid unduly favoring futures market prices as forecasts, the futures prices are considered as forecasts of the spot prices predicted by most of the econometric firms.[2] As a comparison of futures prices with other spot prices has revealed, these spot prices also appear to be the ones most closely related to the futures market near the time of delivery.

The Comparison of Forecasts

The statistics discussed above are reported in table 2 for the eight respective commodities. (Note that the units reported in table 3 are based upon the measurements defined in fn. 1) An examination of these results reveals some interesting quantitative relationships among alternative forecasters. For example, the variation in root mean squared errors and percentage errors among econometric forecasters is fairly large for given forecasting horizons for wheat, corn, and soybean meal, with differences in root mean-squared percentage error ranging up to over 10%. On the other hand, for cattle—and to a lesser extent cotton, soybeans, and soybean oil—all econometric firms maintain similar magnitudes of error.

Generally, Chase forecasts perform better for wheat and live cattle, Wharton or DRI for corn, Doanes for cotton, and DRI for hogs; but there is no clear dominance of one forecaster over another in most cases when all horizons are considered. Generally, one would expect short horizon forecasts to be more accurate than long horizon forecasts. Forecast error, indeed, tends to increase with forecast horizon for wheat, hogs, cattle, and most soybean derivative forecasts. On the other hand, the forecasts for soybean price seem to be more accurate for longer horizons than for short horizons. This observation may be due to an unusual market trend over the particular period of this study, but it could also be due to the relatively volatile nature of the soybean market. For example, the soybean futures market generally is thought to be a more active and fluctuating market, which makes it relatively attractive to speculators. For this reason, phenomena unrelated to the cash market may play a greater role in short-run trading and price fluctuations, so that the more predictable market movements only tend to occur over a longer time horizon. Indeed, comparing across commodity markets on the basis of root mean-squared percentage errors, the soybean market seems to be much less predictable in the short run than other commodity markets (with the possible exception of soybean derivative markets). The corn and wheat markets, which are generally thought to be much less active and more stable, are more predictable over all horizons (in a mean forecast sense) than the other commodities.

Econometric Forecasting versus Futures Markets

One objective of this paper is to examine the performance of various econometric models using the futures market prices as a standard of comparison. To develop some summary information in this respect, rankings of the five econometric against futures forecasts are given in table 3. These results reveal that no one model performs consistently better over all commodities. This variation in performance may be due to a randomness in characteristics *vis-à-vis* important market phenomena in 1977 and 1978; however, using nonparametric test statistics, many of the results are significant (table 3).[3]

Table 3 reveals the following significant results for performance of the commercial ven-

lb.); hogs—Chase, Doanes, DRI, and Wharton, 7-market average price, barrows and gilts ($ per cwt.); and live cattle—Chase, Doanes, DRI, and Wharton, choice 1,100–1,300 pounds slaughter steer price, Omaha ($ per cwt.). The sources for these data series are various issues of the following publications of the U.S. Economics, Statistics, and Cooperative Service: *Wheat Situation, Feed Situation, Livestock and Meat Situation, Fats and Oils Situation*, and *Cotton and Wool Situation*.

[2] Note that delivery costs are reflected in the basis, i.e., the difference between the futures and the spot price for a specific location. Our analysis assumes that the basis due to commissions, capital costs, risk, and the like is approximately constant (at least over the two-year period of this study) in either an additive or multiplicative sense. Thus, the price forecasts are analyzed only in terms of their deviations from longer-term average levels in either an absolute or percentage sense.

[3] The nonparametric tests assume independence of ranks over forecast horizons. Because the forecasts over various horizons are made under the same (possibly erroneous) model specifications, one must bear in mind the possibility of correlated ranks in which case the test statistics are biased toward significance.

[a] Root mean squared error.
[b] Root mean squared percentage error.

dors. Chase forecasts are relatively superior for wheat and live cattle and relatively inferior for soybean oil. Doanes performs well for cotton, soybeans, and live cattle; but none of these results are supported by both comparisons. The DRI forecasts are relatively good for hogs and poor for wheat. Wharton performs relatively poorly in forecasting soybeans and possibly soybean meal but relatively well for corn and cotton, depending on comparison. The USDA does well for soybean meal but is relatively a poor forecaster for hogs, live cattle, and possibly wheat.

Comparison of the econometric forecasts with the futures prices, however, reveals some interesting observations. First of all, futures prices tend to dominate the econometric models in forecasting soybean oil, soybean meal, and soybean prices. In fact, soybean meal is the only commodity where any forecast completely dominates all others over all time horizons (in the comparable forecast case). Also, however, futures prices perform quite well as forecasters for wheat and hogs. Over all commodities and horizons, the average rank of the futures forecast is less than 3, which suggests that, at the mode, the econometric models are not able to forecast as well as the futures market. Furthermore, the futures market is the only source of price information other than Doanes which is not significantly inferior for any commodity; and the futures market is significantly superior for as many as four of the eight commodities based on comparable forecasts (table 3, last column), while Doanes is only significantly superior for two commodities at most (and at lower significance levels).

In terms of the earlier discussion, it appears that futures market inefficiencies are not serious and (or) that econometric models do a poorer job of including all relevant exogenous forces, forecasting them, and transforming them into price forecasts than the aggregate intelligence of the futures market. By comparison, average ranks of comparable forecasts over the first three forecast horizons (those horizons where all forecasters produce forecasts) for each respective forecaster are Chase, 3.27; Doanes, 3.17; DRI, 3.5; Wharton, 3.19; USDA, 4.19; and futures, 2.75. Note that these average ranks are slightly biased against Doanes and, to a lesser extent, the USDA since they do not produce forecasts for some of the commodities; thus, average ranks are a bit higher in the commodities which they forecast than in those they do not.

Turning to issues related to time horizon, since traders in the futures market are often closer to cash market phenomena and are often able to make use of new information more quickly than econometric firms, one might expect futures markets to perform better as short-term forecasters. On the other hand, econometric forecasts may be based on better structural information and more careful, longer-run forecasts of the more important exogenous forces. Indeed, examining only the results for comparable forecasts associated with futures market ranks in the lower right-hand side of table 3, the econometric forecasts are generally favored on average for a one-quarter horizon in the case of corn and cotton; corn, cotton, and cattle for a two-quarter horizon; corn and cattle for a three-quarter horizon; and hogs and cattle for a four-quarter horizon. On the other hand, the futures market outranks all commercial econometric forecasts in three of eight cases for a one-quarter horizon, one of eight cases for a two-quarter horizon, four of eight cases for a three-quarter horizon, and, finally, five of eight cases for a four-quarter horizon. Thus, there is no apparent increase in the superiority of the econometric forecasts with a time horizon as one might expect.

Decomposition of Forecast Error

Some additional information regarding the value of various price forecasts for individual decision makers can be gleaned from a de-

[c] Number of observations.

composition of forecast errors. For the case where both estimated and actual prices are varying in time, the mean squared error can be decomposed following

$$\frac{1}{n}\sum_{t=1}^{n}(Y_t - X_t)^2 = (\bar{Y} - \bar{X})^2 + \frac{1}{n}\sum_{t=1}^{n}(X_t - \bar{X})^2 + \frac{1}{n}\sum_{t=1}^{n}(Y_t - \bar{Y})^2 - \frac{2}{n}\sum_{t=1}(Y_t - \bar{Y})(X_t - \bar{X}) = (\bar{Y} - \bar{X})^2 + \sigma_X{}^2 + \sigma_Y{}^2 - 2\sigma_{XY},$$

where Y and X are predicted and actual prices, n is the number of observations for a given forecaster and time horizon, $\bar{Y}$ and $\bar{X}$ represent respective sample means, $\sigma_X{}^2$ and $\sigma_Y{}^2$ represent respective sample variances, and σ_{XY} is the sample covariance of X and Y. Thus, the mean squared error decomposes into the bias squared, the variance of the forecast, the variance of the actual price, and minus twice the covariance between the two. This decomposition is reported in table 4. The first term, $(\bar{Y} - \bar{X})^2$, is recorded as the bias squared; the term $\sigma_Y{}^2$ is recorded as the forecast variance; the term $\sigma_X{}^2$ is recorded as the actual variance; and the term $-2\sigma_{XY}$ is recorded as the covariance component. The sum of these four components is the mean squared error, the square root of which is directly comparable to those measures reported in table 2, except that in table 4 only new forecasts are used for the computations. Note that the correlation coefficient is $-\frac{1}{2}$ times the covariance component divided by the square root of the product of forecast variance and actual variance.

One of the interesting implications of table 4 is that not all forecasters seem to be making the same types of errors. For example, in wheat the futures forecast makes most of its errors because of variability in future prices. This implies that some filter might (although not necessarily) average out some of the variability and provide a better forecast. The USDA, on the other hand, makes a large share of its wheat price forecasting errors because of negative covariance between actual and predicted prices, such as might be the case when turning points are missed. The commercial firms such as Chase, DRI, and Wharton make a larger share of their wheat price errors because of bias. Somewhat similar conclusions hold for soybeans.

These same conclusions do not hold for other commodities, however. For example, the econometric firms are remarkably unbiased for cotton, while forecast errors for most econometric models are much more attributable to covariance *vis-à-vis* the futures market. All forecasters commit most of their errors because of bias in hog price forecasting.

It is interesting to consider the extent to which bias can be traded off for lower forecast variance or for lower covariance between forecast and actual prices by choosing one forecast versus another. In point of fact, if a firm's profits are inversely related to forecast error, then a risk-neutral firm may prefer lower bias and be willing to live with higher variance. A risk-averse firm, however, may be willing to use biased forecasts to get greater precision. Also, if costly adjustments are incurred when forecasts are highly variable, then cost-efficiency criteria may also favor lower forecast variance over reduced bias, etc. With this in mind, the wheat price forecasting results, for example, imply that a risk-neutral firm may find futures prices quite adequate forecasters, while a similar risk-averse firm with high cost of adjustment may prefer the lower variability of the Chase, Doanes, or even DRI forecast even though the bias is substantially higher.

These considerations suggest that econometric forecasters with similar overall forecasting ability may be able to differentiate substantially their product to capture specific segments of the market. For example, in soybean price forecasting, the futures prices may appeal to a risk-neutral decision maker, while increasingly risk-averse decision makers or those with higher adjustment costs may turn to Wharton and then to Chase or Doanes as bias is traded for reduced forecast variance (based on one- to three-quarter horizons). Some of these trade-offs are particularly remarkable for soybean oil and meal, where Chase makes most of its errors due to bias, while other forecasters are nearly unbiased.

Finally, comparing the decomposition of errors across commodities, it is interesting to observe the correlation coefficient of forecasts with actual prices after removing bias and variability. For firms interested in turning points and magnitudes of changes, the covariance component may have overriding importance. A positive correlation is reflected by a negative covariance component, i.e., one that

Table 4. Decomposition of Forecast Error for Wheat, Corn, Cotton, Soybeans, Live Cattle, Hogs, Soybean Oil, and Soybean Meal, December 1976, through December 1978

observations from two to five months before contract maturity and regression coefficients were less than one for all eight months of lagged observation.

Relative to lagged futures, lagged cash prices yielded mixed results. In general, there is little evidence to support the superiority of either lagged futures or cash prices as forecasts.

Results for live hogs indicate that the statistical hypotheses for all lagged futures observations were accepted. For lagged cash prices, only the hypotheses regarding regression coefficients for observations from three to six months before contract maturity during periods of declining prices were rejected.

The foregoing suggests that live cattle futures have been reliable forecasts during periods of rising prices, but unreliable when prices declined. Second, there was little difference in the forecasting performance of live cattle futures prices relative to lagged cash prices. Third, relative to live cattle futures, live hog futures exhibited superior performance during periods of declining prices. Finally, forecasting performance of live hog futures relative to lagged cash hog prices was marginally superior.

Why the difference in forecasting performance of live hog futures relative to live cattle? The results are consistent with the argument regarding the nature of supply response. Because female slaughter in the beef sector during periods of herd liquidation is a much more significant proportion of total slaughter than for the pork sector, this element of supply response may be more difficult to assess in forecasting total supply and therefore prices of cattle. Hence the poorer forecasting performance of live cattle futures.

Hypothesis (c): Forecasting Performance Differs Seasonally

Differential performance on a seasonal basis may be expected for two reasons. First, seasonal supply and demand factors affect the cash prices of both products. These may be interpreted differently by futures traders. Second, Leuthold (1975) has noted that there is substantial seasonal variation in the volume of futures trading, which could be a factor in forecasting performance.

To determine whether seasonal differences exist, the dummy variable formulation was estimated with the data separated by contract month. Data were grouped by calculating index numbers of monthly cash prices over the entire period for which data were available. If the monthly index values for two months were similar, they were aggregated into a single dummy variable in order to preserve degrees of freedom. The base variable for cattle includes prices for October and December; α_1, β_1 are coefficients for prices in February and April; α_2, β_2 are coefficients for prices in June; and α_3, β_3 are coefficients for prices in August. For hogs, the base variable also includes prices for October and December; and four dummy variables were specified to include February, April, June and July/August, respectively.

The results for cattle show that both cash and futures prices were unbiased forecasts for all months in which futures contracts matured and for observations taken from one to eight months before contract maturity. However, the regression coefficients were different than one for futures prices observed from two to eight months before the October and December contracts matured and from three to eight months before the February and April contracts matured. In contrast, the hypotheses regarding the regression coefficients for lagged cash prices were accepted for six of the eight lagged months for February and April. This suggests that, while cattle futures were generally unbiased and explained movements in cash prices for June and August over the thirteen years of the analysis, they did not generally forecast price movements well for October, December, February, and April. Furthermore, lagged futures prices forecast movements relatively less well than did lagged cash prices for these four months.

The results for hogs indicate that all the futures prices met both the bias and regression coefficient criteria for the seasonal analysis. Lagged cash prices all were unbiased, but the regression coefficient criterion was rejected in four of the lagged months for October/December, two for February, and one for April. According to the criteria established, it is clear that the forecasting performance of live hog futures was acceptable and somewhat better than for lagged cash prices during the fall and winter months. Comparing live hog and live cattle futures, it is also clear that the performance of the live hog market was superior during the fall, winter, and spring months.

Again one questions the reason for the relatively poorer performance of live cattle fu-

tures. We suggest that, because there is a more distinct seasonal pattern in cash hog prices than in cash cattle prices, traders in hog futures are better able to anticipate seasonal price variations. This seasonal pattern appears to be reflected generally in live hog futures prices.

Hypothesis (d): Forecasting Performance Is Different When Economic Conditions Are Unstable Than When They Are Stable

General economic conditions, including prices in the livestock and grain sectors, have been relatively unstable since mid-1973. This period has been characterized by unprecedented inflation, substantial intervention in markets through government policy (e.g., retail price ceilings on meat and an export embargo on soybeans) and unprecedented variations in feed grain prices because of substantial fluctuations in export sales. The effects of inflation and policy intervention on prices are difficult to anticipate. Variations in feed grain prices affect profitability of livestock production and therefore have impacts on supply response. The latter affects livestock prices. Feed grain prices can be a determinant of breeding decisions, female slaughter, the age and weight at which livestock are placed on feed, the length of time they are maintained on feed and, therefore, the weight at which they are slaughtered. The more variable feedgrain prices, the more impact they may have on supply response and the more difficult will be the task of forecasting supply and prices. Thus, our hypothesis is that the forecasting performance of futures prices is better when economic conditions are relatively stable.

To delineate stable and unstable periods, weekly corn prices were plotted over the period from 1965 through 1977. These data showed clearly that both the level and variability of corn prices were substantially higher from May 1973 through the end of 1977 than during the preceding period. Hence the livestock price data were disaggregated to include a relatively stable period before June 1973 (beginning in 1965 for cattle and 1970 for hogs) and an unstable period from June 1973 through the end of 1977. Separate equations were estimated for each period and commodity.

Results for cattle indicate that, before June 1973, both lagged futures and lagged cash prices met the criteria established for prices lagged from one to eight months. However after 1973, while neither lagged futures nor lagged cash prices were biased, the regression coefficients were less than one for all but one month lags. In fact, several regressions resulted in negative coefficients.

For hogs, similar results were obtained, except that both futures and cash prices generally were biased forecasts and the regression coefficients were less than one during the period of variable feed prices. The rather obvious inference to be drawn is that livestock futures performed the forecasting function acceptably when economic conditions were relatively stable, but were unable to forecast well when they were unstable.

Conclusions

Consider the dichotomy about the role of futures for noninventory commodities addressed at the paper's outset. Should livestock futures be regarded as forecasting agencies or as markets for rational price formation? Based on this analysis, the live cattle market clearly has not performed the forecasting function well. Cattle futures appear to add little forecasting information beyond that available in lagged cash prices. Live hog futures appear to perform the forecasting function well relative to both live cattle futures and lagged cash prices, except during periods when economic conditions are unstable. However, the true test of a forecasting mechanism is its performance when forecasting is most difficult. Live hog futures fail the test. Based on these findings, Leuthold and Hartman's suggestion that better informed traders in livestock futures could improve the market's forecasting performance seems fully warranted.

Do livestock futures promote rational price formation? If so, then producers will respond to them and, following Gray's reasoning, the resulting supply response will be incorporated into traders' expectations. Futures prices will then become better forecasts as contract maturity approaches. The lags investigated here are sufficiently long to elicit at least a short-term supply response. Yet, in most cases where forecasting performance was originally poor, it did not improve as contract maturity approached. Hence, the performance of cattle and hog futures as a rational price formation agency is suspect.

Several studies of the hedging potential of livestock futures markets were cited at the

beginning of this paper. They conclude that routine hedging can enhance income stability. This implies that livestock futures markets act as agencies for rational price formation. However, these studies were based on relatively long, aggregated time series. To improve the analysis of livestock futures markets as hedging mechanisms and rational price formation markets, similar analysis should be conducted over disaggregated series as we have done.

Farmers' Credit Risks and Liquidity Management

Peter J. Barry, C. B. Baker, and Luis R. Sanint

Credit risks are unanticipated variations in costs and availability of credit that arise from forces in financial markets or from lenders' responses to risks in agricultural markets and farmers' creditworthiness. An extension of mean-variance portfolio theory shows how credit risks combine with other financial and business risks to determine total risk. Empirical evidence from lender surveys about risks shows that farmers' credit is positively correlated with changes in farm income, although the correlation is stronger for capital credit than for operating credit, and that variability in fund availability from rural banks has contributed to high credit risks.

Key words: agricultural finance, credit, liquidity portfolio theory, risk management.

Liquidity management is a principal means by which farmers cope with variations in cash flows that arise from uncertain commodity prices, yields, and production costs. The farmer's objective is to assure that cash can be generated quickly and efficiently in order to meet cash demands. Previous studies by Baker (1966, 1968), Baker and Bhargava, Barry and Baker, and Barry and Willmann, have provided much insight on the role of credit in farmers' liquidity management, how credit appraisals differ among lenders, and how farmers' perceptions of these appraisals interact with their managerial decisions. However, these credit concepts and measurement procedures are developed in deterministic terms so that once the composition of credit is known, it is modeled as though it can be relied upon with complete certainty.

Farmers' reliance on credit as a source of liquidity introduces risks in terms of lenders' responses to changing conditions in agriculture and in financial markets that influence their lending decisions and resulting credit availability. These uncertain responses give credit the characteristics of a random variable whose properties can be expressed through the farmers' cost of borrowing. Thus, farmers' credit risk is an added element of their portfolio risk that has not been accounted for in prior analyses. It increases with financial leverage and must be taken into account inasmuch as credit management is a component of overall farm business management.

The purposes of this paper are to further develop concepts underlying farmers' credit risks, to show through an extension of portfolio theory how credit risk may influence farmers' debt use and, thus, firm organization, and to evaluate alternative methods for empirically measuring credit risk. Some empirical evidence is reported on credit risk associated with variations in farmers' incomes and with changes in availability of loan funds at rural banks. Managerial consequences also are developed, using concepts of business and financial risk.

Liquidity Concepts

Liquidity concepts are based on relationships between a firm's composite value of assets and cash proceeds expected from each asset's sale to meet liquidity needs. An asset is considered perfectly liquid if its sale generates cash equal to or greater than the reduction in value of the firm resulting from the sale (Baker 1966). Assets become less liquid as their potential sale reduces the firm's value by more than their expected sales value. Factors generally considered to influence an asset's liquidity include transactions costs, marketability, time allowed for liquidation, liquidity risk, and the asset's impact on a firm's capital integrity.

Peter J. Barry and C. B. Baker are professors of agricultural economics at the University of Illinois; Luis R. Sanint is a former research assistant at Texas A&M University, now a research economist with the U.S. Department of Agriculture.

Transactions costs include commission charges, installation and assembly costs, transportation and storage costs, opportunity costs, and losses in transit. Marketability refers to characteristics of the market in which the asset is traded. Included are quality of market information, volume of trading, number of participants, development of secondary markets, and other factors that cause differences between an asset's purchase and sale price at a given time (Modigliani). Timing refers to urgency of need for funds with sale proceeds generally increasing as time available for liquidation increases (Pierce). Liquidity risk refers to the relationship between asset values and a firm's stochastic demands for cash (Chen, Jen, Zionts). An asset yielding a high return when cash demand is high is liquidity-preferred. One yielding a low return when cash demand is high is liquidity-averse, and one whose return is independent of cash demand is liquidity-neutral. Among liquidity-neutral assets, those with lower variances are considered to have higher liquidity (Cropper). Capital integrity refers to the importance of an asset's income-generating role in the firm. Liquidations of current assets, like inventories or goods in production, are part of the firm's usual operations. Their effect on firm value largely is reflected directly in its balance sheet. In contrast, liquidations of other assets like machines, breeding livestock, and real estate deplete the firm's income-generating capacity and may reduce the firm's value by more than the asset's sales value. These assets then are illiquid, even though some may have high marketability, low transactions costs, or low liquidity risk.

Holding credit reserves as a source of liquidity provides a means of generating cash that avoids the costs associated with liquidating productive assets to meet cash demands and then reacquiring assets later when adverse conditions have passed. Credit reserves also substitute for cash or cash substitutes as a source of liquidity. Using credit does not greatly disturb a farm's asset structure or production organization, its transactions costs are relatively low, and institutional sources of loan funds generally are available in rural financial markets. However, costs of maintaining and borrowing from credit reserves must be considered. Holding reserves reduces returns from investment opportunities that are foregone from further financial leverage; interest is paid when loans occur; and noninterest charges like deposit balances and loan fees sometimes occur to compensate lenders for establishing lines of credit. Moreover, financial risk must be accounted for in borrowing (Gabriel and Baker), and there is uncertainty about future costs and availability of credit.

Identifying forces affecting the supply of available credit and developing procedures for measuring a farmer's credit risk are complicated by the complexity of credit determinants, Some credit determinants originate in financial markets. Macroconditions attributed to monetary and fiscal policies, structural characteristics of financial markets, and aggregate economic performance may influence costs and availability of loan funds; so may microconditions that characterize financial intermediaries. These financial market conditions are far removed from farmers' operating environments and may have little or no influence on farmers' cash demands. They influence, but are not influenced by, farmers' credit management. Hence, farmers can only monitor them as part of their financial environment.

Other determinants of credit supply originate in agriculture through macroeffects of supply-demand conditions for commodities and resources, and through microeffects of farmer-lender relationships that reflect the lenders' concept of farmers' creditworthiness. Creditworthiness is evaluated on the basis of evidence farmers supply to assure lenders that lending risks will be minimal and that debt servicing will meet the terms of the loan contract.

In gaining these assurances, lenders consider a farmer's personal characteristics and credit history, managerial qualities, wealth position including collateral offered as loan security, and income and repayment expectations. These financial factors often are translated into credit limits through commonly used rules-of-thumb.[1] The limits may be modified further to reflect managerial characteristics, security position, and financing practices of individual operators, as in the cases of younger, low equity borrowers, unsecured notes, risk-reducing practices, installment contracts, trade credit, and so on.

[1] Examples are lenders' willingness to loan up to 75% of farmland's current market value, to require a 40% margin of equity in cattle placed on feed, to loan up to 75% of a crop's expected sale value, and to aim for an overall debt-equity ratio not to exceed 1.0.

The lending rules reflect risk premiums that lenders associate with the contingency of having to liquidate the various assets being financed, while still providing sufficient funds to cover the indebtedness. The lending rules produce a credit limit. The difference between the credit limit and the actual loan disbursement is the credit reserve. Moreover, as borrowing occurs, the farmer's remaining credit reserve becomes more volatile in response to changes in asset values and income expectations. Hence, credit reserves are expected to decline (increase) with lower (higher) market values of crops, livestock, machines, and land at rates that increase as leverage increases.[2]

These features of creditworthiness mean that the effects of asset characteristics on liquidity are similar, whether evaluated by a farmer or by a lender. That is, the effects of transactions costs, marketability, time, liquidity risk, and capital integrity are about the same, whether asset liquidation occurs by a farmer or by a lender, in the event that a loan reaches forceable liquidation. In general, then, the liquidity risk characteristics of assets extend to holdings of credit reserves. Credit is positively correlated with net values of assets, given the firm's liability structure, and is positively correlated with net income expectations, given the repayment commitments.

Credit Risk and Portfolio Analysis

Risks associated with costs and availability of credit are an added element of farmers' portfolio risk that influence debt use and resulting capital structure for risk-averse farmers. Hence, it is appropriate to include the effects of credit risk in farm firm analysis in order to evaluate its effects on farmers' portfolios and to serve as a guide for further empirical analysis. These effects are shown here by extending the mean-variance portfolio model explicitly to include risk properties for costs of borrowing, and by deriving an expected utility-maximizing farm portfolio that accounts for these measures of credit risk.

The mean-variance approach is well known and much debated, especially about the limited generality of its assumptions. However, its widespread use (Robison and Brake), its explicit measures of risk, and rigorous demonstration (Tsiang; Levy and Markowitz) of its usefulness as an approximate method for portfolio selection help make it an acceptable model for showing the portfolio effects of credit risk.

Consider a risk-averse farmer who must choose a level of debt (D) with which to leverage equity (E) in financing risky production with total assets (A). Expected returns before interest and taxes and variance from investment in risky assets are designated $\bar{r}$ and σ_r^2, respectively. When credit is specified only in deterministic terms, the cost of using credit in borrowing is expressed as rate $i = i_b + i_r$, with both components having zero variance. Component i_b is the interest rate paid the lender, and liquidity premium i_r is the farmer's value of the credit reserve. When credit is treated as a random variable, the cost of using credit in borrowing is expressed as expected rate $\bar{i}$, with variance σ_i^2, and covariance σ_{ri} with returns from risky assets. Hence, risk is treated in probabilistic terms with variance used to measure likelihoods of events occurring that produce results less than expected.

To show a closed-form solution, let the farmer's utility function be approximated by the negative exponential,

$$U(\pi) = 1 - e^{-2\lambda\pi}, \tag{1}$$

where λ is the degree of risk aversion ($\lambda > 0$), and π is the level of income. Freund has shown that maximizing the expected value of a negative exponential integrated over a normal density function, as is assumed for r and i, is equivalent to maximizing

$$E[U(\pi)] = E(\pi) - \lambda\sigma_\pi^2. \tag{2}$$

Notation $E(\pi)$ and σ_π^2 now represent the expected profits and variance, respectively, of the farmer's portfolio. Expected profits are defined as the returns to assets less the cost of borrowing

$$\pi = \bar{r}A - iD. \tag{3}$$

Portfolio variance is

$$\sigma_\pi^2 = \sigma_r^2A^2, \tag{4a}$$

where cost of borrowing is deterministic, and

$$\sigma_\pi^2 = \sigma_r^2A^2 + \sigma_i^2D^2 - 2AD\sigma_{ri}, \tag{4b}$$

where the cost of borrowing is a random variable. Expression (4b) is the variance of the

[2] Credit relationships discussed here are not specific to any one lender. The concepts can be extended to include risks of credit availability from primary lenders and from secondary lenders like merchants and dealers, finance companies, and government agencies.

difference between two random variables. Hence, the covariance term has a negative sign preceding it, indicating that the lower (higher) is the correlation between r and i, the greater is the increase (reduction) in total portfolio variance (Fama, pp. 226–9).

For the deterministic credit case, substituting the expressions in equations (3) and (4a) into equation (2) yields

$$(5) \quad E[U(\pi)] = E[\bar{r}A - iD] - \lambda[\sigma_r^2 A^2].$$

Substituting $D + E = A$ and considering the level of debt (D) as the decision variable, the first-order condition for an expected utility-maximizing level D^* is

$$(6) \quad dU(\pi)/dD = \bar{r} - i - 2\lambda\sigma_r^2 D - 2\lambda\sigma_r^2 E = 0,$$

which gives optimal debt of

$$(7) \quad D^* = \frac{\bar{r} - i - 2\lambda\sigma_r^2 E}{2\lambda\sigma_r^2}.$$

Differentiating (7) with respect to $\bar{r}$, i, λ, σ_r^2, and E shows the following comparative static properties:

$$(8a) \quad dD^*/d\bar{r} = \frac{1}{2\lambda\sigma_r^2} > 0,$$

$$(8b) \quad dD^*/di = \frac{-1}{2\lambda\sigma_r^2} < 0,$$

$$(8c) \quad dD^*/dE = -1 < 0,$$

$$(8d) \quad dD^*/d\lambda = \frac{-\bar{r} + i}{2\lambda^2\sigma_r^2} < 0,$$

$$(8e) \quad dD^*/d\sigma_r^2 = \frac{-\bar{r} + i}{2\lambda\sigma_r^4} < 0.$$

Optimum debt is positively related to changes in expected returns on assets and inversely related to changes in costs of borrowing, equity, variance of returns, and risk aversion.[3] In the latter two cases, the inverse relationships hold as long as expected return on assets is greater than the cost of borrowing.

When credit risks are introduced, the expression for expected utility maximization becomes

$$(9) \quad E[U(\pi)] = E[\bar{r}A - \bar{i}D] - \lambda[\sigma_r^2 A^2 + \sigma_i^2 D^2 - 2AD\sigma_{ri}].$$

Again, substituting $D + E = A$ and considering the level of debt as the decision variable, the first-order condition for an expected utility-maximizing level D^* is

$$(10) \quad dU(\pi) = \bar{r} - \bar{i} - 2\lambda\sigma_r^2 D - 2\lambda\sigma_r^2 E - 2\lambda\sigma_i^2 D + 4\lambda D\sigma s_{ri} + 2\lambda E\sigma_{ri} = 0,$$

which gives optimal debt of

$$(11) \quad D^* = \frac{\bar{r} - \bar{i} - 2\lambda E(\sigma_r^2 - \sigma_{ri})}{2\lambda(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})}.$$

Comparison of expressions for optimal debt in equations (7) and (11) indicates that the addition of risk measures for credit will mostly warrant lower use of debt, although the result depends strongly on the level of covariance σ_{ri}. If, for example, covariance is zero, then debt use clearly is less in expression (11). However, if covariance is strongly positive, then optimal debt could be higher in expression (11). This is shown by setting equations (7) and (11) equal to each other and solving for σ_{ri}. The result is

$$(12) \quad \hat{\sigma}_{ri} = \frac{\sigma_i^2(2\lambda\sigma_r^2 E - \bar{r} + \bar{i})}{2(\lambda\sigma_r^2 E - \bar{r} + \bar{i})}.$$

As long as the actual σ_{ri} is less than $\hat{\sigma}_{ri}$, optimal debt in equation (11) will be less than optimal debt in equation (7). Suppose, for example, that the variables have the following values: $\bar{r} = .12$, $\bar{i} = .08$, $\sigma_r^2 = .0016$, $\sigma_i^2 = .0004$, $\lambda = .0000624$, and $E = \$100{,}000$. The values: $\bar{r} = .12$, $\bar{i} = .08$, $\sigma_r^2 = .0016$, $\sigma_i^2 = .0004$, $\lambda = .0000624$, and $E = \$100{,}000$. The pression (11) to exceed its value in (7).

Comparative static properties for equation (11) are

$$(13a) \quad dD^*/d\bar{r} = \frac{1}{2\lambda(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})} > 0,$$

$$(13b) \quad dD^*/d\bar{i} = \frac{-1}{2\lambda[\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})} < 0,$$

$$(13c) \quad dD^*/d\lambda = \frac{-\bar{r} + \bar{i}}{2\lambda^2(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})} < 0,$$

$$(13d) \quad dD^*/d\sigma_r^2 = \frac{-\bar{r} + \bar{i} - 2\lambda E(\sigma_i^2 - \sigma_{ri})}{2\lambda(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})^2},$$

$$(13e) \quad dD^*/dE = \frac{-(\sigma_r^2 - \sigma_{ri})}{\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri}},$$

[3] The trade-off between equity and debt in expression (8c) appears unusual. However, it is consistent with the constant absolute risk-aversion assumption for a negative exponential utility function. Hence, for this utility specification, increasing wealth (E) does not cause a change in holdings of risky assets (A); rather, it allows a reduction in risk-free debt while holding constant the level of risky assets. Holdings of risky assets, and thus debt, would only increase with increases in equity if risk aversion (λ) decreases or if some other parameter value changes accordingly.

$$(13f)\quad dD^*/d\sigma_i^2 = \frac{-\bar{r} + \bar{i} + 2\lambda E(\sigma_r^2 - \sigma_{ri})}{2\lambda(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})^2}$$

$$(13g)\quad dD^*/d\sigma_{ri} = \frac{\bar{r} - \bar{i} + \lambda E(\sigma_i^2 - \sigma_r^2)}{\lambda(\sigma_r^2 + \sigma_i^2 - 2\sigma_{ri})^2}.$$

These results are more ambiguous than in expressions (8a) through (8e). In all cases, the denominator values are nonnegative. However, only (13a) and (13b) have definitive numerator values: debt use is positively related to changes in asset returns and inversely related to borrowing costs. The relationship between debt and risk aversion also is inverse if expected asset returns exceed expected borrowing costs. Debt responses to changes in other parameters cannot be fully evaluated without knowing their values.

Measuring Credit Risks

Measuring farmers' credit risks would be simplified if lenders' risk responses were expressed solely as adjustments in risk premiums on interest rates for loans, rather than through nonprice responses. Then, the response of interest rates on individual loans to changes in farm risk would show the part of farmers' credit risk that is attributed to their creditworthiness. Similarly, the relationship between interest rate changes induced by conditions in financial markets and changes in farm loan demand would show the part of credit risk attributed to market forces. However, measurement of credit risk is hampered by lack of explicit risk pricing on loans by lenders to reflect their judgment about farmers' creditworthiness and availability of loan funds.

Nonprice Credit Responses

Interest rates on loans from major nonreal estate farm lenders like rural banks and production credit associations seldom vary much among individual borrowers. Even when rates do vary, the response may be more to differences in loan sizes and costs of lending than to differences in risk. Instead, lenders' risk responses to differences in farmers' creditworthiness primarily occur in nonprice ways that include differing loan limits among borrowers, and differences in security requirements, loan maturities, loan supervision and documentation, and other means of credit administration (Baker1968; Barry and Willmann; Robison and Barry).

Changes in availability and cost of loan funds that arise from forces in financial markets are more likely to be expressed in interest rates, although differences in sources and uses of funds among major types of farm lenders cause other differences in their loan policies. Farm Credit System (FCS) lenders, for example, acquire most of their loan funds from national financial markets through sales of consolidated bonds or discount notes that occur under highly competitive conditions. Hence, their access to loan funds is constrained only by their capacity to pay market interest rates. In turn, loan funds are priced to farm borrowers with variable interest rates that are adjusted periodically for changes in average cost of funds, reserve or capital requirements, or other intermediation costs. These loans also are considered exempt from state usury laws. So, observations on changes in interest rates on FCS loans should closely indicate the part of farmers' credit risk that is attributed to changes in financial market conditions.

In contrast, factors affecting fund availability for rural banks have been much more insulated from national financial markets than for FCS and for larger urban banks. Rural banks rely heavily on local markets for attracting deposits as their major source of funds. Demand deposits have had no interest cost, and historically rates on all time deposits but large, negotiable certificates of deposits have had legal limits. In periods of rising interest rates, these banks often experience disintermediation as deposit funds are attracted to other investments (Benjamin).[4] These banks also are subject to considerable fluctuation in farm and farm-related loan demands in their local market. Combined effects of these conditions have generated periodic stresses in rural banks' liquidity and relatively high fluctuation in availability of loan funds for farmers. Moreover, relatively few farm loans from rural banks are priced with variable interest rates.

---

[4] Availability in late 1978 of money market certificates with 6-month maturities and with minimum denominations of $10,000, and availability of 30-month time deposits both of whose rates are indexed to U.S. government securities appear to have greatly freed up banks' capacity to bid for deposit funds. These developments together with anticipated phase-out of regulation Q and liberalization of usury limits on loan rates may bring a substantial shift during the 1980s to reliance on price rather than nonprice credit responses by rural banks. However, the relative uses of price and nonprice responses to individual loan customers may still continue to depend heavily on levels of loan competition in rural financial markets.

Data from the Federal Reserve System indicate that in early 1980 only about 11½% of the amount of farm loans by U.S. banks with less than $400 million in total assets occurred with a floating (variable) rate. Use of floating rates increased slightly with size of farm loans and increased greatly for the largest banks.

Lenders' nonprice responses to changes in farm risks and to changes in financial market conditions, especially in rural banks, mean that attempting to measure linkages between historic changes in interest rates, farm risks, and farm loan demands is not a fully effective way to reflect farm credit risks. Instead, estimates are needed on how lenders' nonprice responses are related to farm risks and farm loan demands. Moreover, the lenders' nonprice responses also make it difficult to express credit risk in terms of a farmer's costs of borrowing, as occurs in the preceding portfolio analysis.

Costs of Borrowing and Nonprice Responses

The relationship between farmers' costs of borrowing and lenders' nonprice credit responses to risk is shown by using earlier approaches to optimal credit use that account for farmers' liquidity premiums (i_r) on credit reserves (Barry and Baker; Baker and Bhargava). This approach specifies optimal credit use as an equilibrium reflecting equality at the margin between a payoff schedule from using borrowed funds in the farm business and a cost-of-borrowing schedule that includes both the interest obligation to the lender and a credit reservation price reflecting the farmer's liquidity premium on the maintained credit reserve. The liquidity premium signifies the liquidity risk component of the farmer's total portfolio risk and is determined by the level of risk aversion.

Panel A of figure 1 shows, for example, that a farmer who exhibits increasing cost of using credit in borrowing V_i and decreasing payoff from borrowing V_L will allocate total credit OC to borrowing in amount OA (70%) and to reserve in amount AC (30%). However, total credit OC now is considered a random variable that is characterized by a probability distribution (P) with mean $\bar{c}$ and standard deviation, σ_c. Once borrowing occurs in amount OA, events that reduce (increase) total credit will be absorbed entirely by reduction (increase) in the credit reserve. A loss (gain) in credit reserve will raise (lower) the farmer's

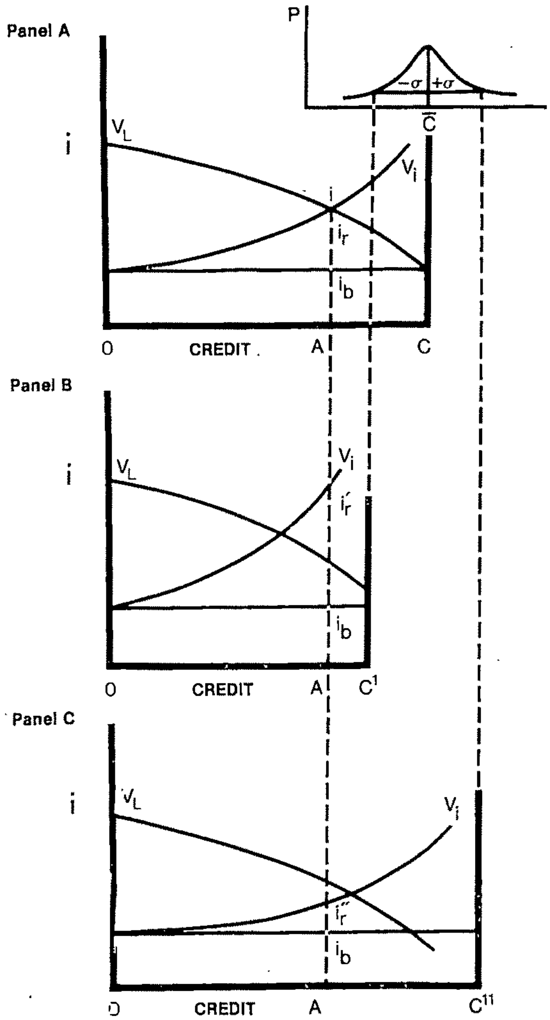

Figure 1. Credit variations and costs

liquidity premium on the remaining reserve, and thereby increase (lower) his total cost of borrowing. This approach assumes that any reduction in credit reserve does not exceed the previously maintained credit reserves, thus forcing asset liquidation or other responses.

Suppose, as indicated in panel B, that total credit is reduced by 20% to OC^1. Original borrowing in amount OA means that 87.5% = (70%/80%) of credit OC^1 now is committed to borrowing, with only 12.5% in reserve. Cost of borrowing increases to $i' = i_b + i_r'$ because of the increased liquidity premium; hence, credit allocation now is nonoptimal. Alternatively, if total credit increases by 20% to OC'' (panel C), borrowing of OA means that 58% = (70%/120%) of credit OC'' now is committed to borrowing, with 42% in reserve. Cost of borrow-

ing then declines to $i'' = i_b + i_r''$ because of the lower liquidity premium.

Hence, variations in the lenders' nonprice responses, shown here by variations in credit limits, are directly related to changes in a farmer's costs of borrowing. Similarly, measures of credit risk shown earlier as variance in borrowing cost and covariance with asset returns can be expressed by the variance of credit and its correlation with factors affecting farmers' financial performance and their demand for loans.

The following analysis focuses on procedures for measuring two components of farmers' credit risk: variation of credit limits in response to risks in farm operations and variation of rural banks' availability of loan funds relative to farmers' loan demands.

Credit Supply and Farm Risks

The procedure for testing the hypothesis that farmers' supply of credit is positively correlated with changes in level of farm income is to simulate a case farm whose level and standard deviation of expected income are estimated from a historic time series of prices, yields, and costs (Sanint). Credit evaluations for the case farm then are elicited from a sample of lenders based on selected gain and loss conditions for farm income. In turn, the likelihoods associated with the gain and loss conditions are derived with risk parameters estimated from the historic series. Thus, a "moderate gain" might be the occurrence of actual income that is 1.0 standard deviation above the expected value; a "favorable gain" might be actual income that is 1.5 standard deviations above the expected value. Similarly, "moderate loss" and "severe loss" might be occurrences of actual incomes that are 1.0 and 1.5 standard deviations, respectively, below the expected value. In this way, the resulting variations in lenders' credit responses can be correlated with variations in farmers' income on the basis of the latter's known statistical properties.

This approach was implemented by following credit elicitation procedures of earlier studies (Baker 1968; Barry and Willmann) where lenders responded through a survey to a case loan request for a representative farming situation. Here, the loan request contains the case farmer's needs for operating expenses, capital expenditures, and other cash obligations for the coming year. The total loan request was set high enough to anticipate the lenders' rejection and designed for deletion of individual items until loan approval was obtained.[5] The approved loan request then signifies total borrowing capacity for each risk condition.

Loan documentation was provided by statements showing financial performance for three risk conditions experienced by the farmer in the preceding year. Two replications of this procedure accounted for the moderate and severe cases. In the first replication lenders were asked to indicate the total loan granted for average and moderate gain-loss conditions experienced by the farmer in the preceding year. The average case assumed that the farmer experienced an average or expected level of performance in the preceding year. The moderate-loss case assumed that the farmer experienced a below-average level of performance in the preceding year with a combination of prices and yields resulting in farm receipt levels that might occur in one out of six years. The moderate-gain case assumed that the farmer experienced above-average performance in the preceding year with prices and yields resulting in gains that might occur in one out of six years. These levels of variation fall roughly within one standard deviation of the expected value.

The second replication differed from the first only in the magnitude of gain and loss experienced by the farmer. Results for the loss and gain cases reflected income conditions that might occur in one out of fifteen years—occurring about 1.5 standard deviations from the expected value. In all cases, the representative farm was characterized as a young, established farmer whose management ability and prior credit record were known. Hence, variations in income were due to random factors and the single year of financial data was set against a longer, successful credit history. Moreover, the sequence of borrowing needs and type of lender were fixed so that these factors did not influence the lenders' credit responses.

---

[5] The operating loan request was designed to cover expenses for crop production and postharvest storage, term-loan payments, and family needs. Most of these outlays reflect fixed obligations that a farmer must meet to continue his operation, although financing needed for crop storage is more flexible because sales from inventory will generate cash for other uses. In contrast, capital purchases for growth, modernization, or replacement offer greater flexibility because they generally can be postponed or cancelled without jeopardizing the firm's immediate operations.

Besides the designation of loan limits for these risk conditions, lenders also were asked about other loan terms that might reflect their response to the case farmer's risk position. Included were interest rates charged on the loan under the stipulated farm income conditions, security or collateral requirements, and any other loan requirements. Thus, while the survey focused on total borrowing capacity for the various farm risk conditions, it also showed other potential risk responses by lenders.

A mail survey was sent in fall 1979 to 101 unit banks and production credit associations (PCAs) in south central and eastern Texas. Banks in the sample were required to have more than $1.2 million in farm loans to assure familiarity with farm financing. Half of the institutions received replication one and the other half received replication two, so that the complexity of risk cases and credit responses was kept to a minimum for the respondents. Fifty lending institutions responded to the survey; however, sixteen responses were voided for several reasons: failure to make this type of loan, large loan size, lack of time to complete the survey. Thirty-four useful responses occurred from twenty-five banks and nine PCAs, with nineteen responses from replication one and fifteen responses from replication two.

Table 1 reports farm financial characteristics and sizes of loan request for the five income cases and averages of the lenders' loan limits for each risk case. Averages of loan granted are indicated in dollar values and as percentages of original loan request. Using percentages accounts for differences in size of the operating loan requests for the loss situations that result from the need for additional, carryover financing.

Survey results indicate a positive relationship between the farm's credit and the level of farm income in the preceding year. The average loan granted and percentages of loans granted are small for the loss situations, and increase as the case farm's income conditions become more favorable. As an example, the percentage of total loan granted increases from 57% for the severe loss to 82% for the favorable gain.

However, the results also indicate that lenders differentiate their credit response between operating and capital loans. Most of the credit adjustment occurs for capital purchases, where the percentage of loan granted ranges from 16% for the severe loss to 69% for the favorable gain. In contrast, credit for operating needs, including carryover loans, is more stable, with percentages of loan granted ranging from 78% for the severe loss to 90% for the favorable gain.

Table 1. Results of Lender Survey for Farmers Income Variation

	Farm Income Conditions					
	Case 1:	Case 2:	Case 3:		Case 4:	Case 5:
	Severe Loss	Moderate Loss	Average Conditions Rep. 1	Average Conditions Rep. 2	Moderate Gain	Favorable Gain

Analysis of variance (ANOV) of lenders' credit responses used a two-way, incomplete, random block design to test for significant differences among levels of farm income and among individual lenders. Preliminary results using one-way ANOV had shown that, while lenders exhibited similar patterns of credit response to changes in farm income, much variation occurred among lenders in the levels of their credit responses across all farm income levels. That is, some lenders exhibited much more liberal credit responses than others. Hence, the two-way approach accounts for both income and individual lender effects in the credit response.

ANOV results show that differences in percentages of total loans granted (total credit) among income levels and among lenders were statistically significant at the 5% level. Furthermore, Duncan's test grouped the loss, average, and gain cases, respectively, but showed no significant differences between the two loss cases or between the two gain cases. ANOV results for capital credit were essentially the same as those for total credit. ANOV for operating credit also showed significant credit responses to changes in income, although the Duncan test identified the severe loss case as the most prominent source of variation. After variation in credit responses attributed to the individual lender effects is removed, resulting partial correlation coefficients between credit and farm income were estimated at .66 for total credit, .82 for capital credit, and .37 for operating credit.

Hence, these results are consistent with the hypothesis that farmers' credit is positively correlated with changes in level of farm income, although the correlation appears stronger for capital credit than for operating credit. In turn, positive correlation between credit and income implies negative correlation between farmers' costs of borrowing and farm income. These numerical results also are consistent with many lenders' written comments on the survey indicating that, when occasional farm losses are anticipated, both farmer and lender must exert careful financial control to see the operation through the adverse period. Restricting capital transactions is a favored control mechanism. Lenders also appear more responsive to the occurrences of loss or gain, than to their actual magnitudes. The credit response for a moderate loss or gain, relative to the average case, appears much more significant than does the credit response between a moderate and severe loss, or between a moderate and favorable gain. This lack of strong response to the extreme conditions may reflect the lender's lack of sharing in the farmer's short-run profits or losses. The credit responses might differ for two or more consecutive years of loss or gain.

Survey responses about other methods of risk response by lenders indicated small differences in security requirements, although security interests in crops, machinery, and equipment were unanimous. In some cases, liens on real estate and credit life insurance were required. No differences in interest rates occurred among lenders or among the risk cases. Banks' market interest rates were high enough to be limited by state usury laws, although PCA rates were not restricted by usury. Hence, nonprice loan methods were the lenders' sole response to the simulated farm risks.

Credit Supply and Loan Fund Availability

To evaluate farmers' credit risks associated with loan fund availability at rural banks, statistical measures are derived for bankers' observations about changes in farm loan demands and changes in fund availability. Bankers' observations are taken from responses of several hundred agricultural member banks in the Seventh Federal Reserve District to quarterly surveys about farm lending conditions conducted by the Federal Reserve Bank of Chicago. Included in these surveys are questions about loan demand, fund availability, loan repayment rates, loan-deposit ratios, and other credit-related information. Bank responses are aggregated and reported as relative frequencies or averages (Federal Reserve Bank of Chicago; Board of Governors of the Federal Reserve System).

On several items, banks are asked whether conditions during the current quarter of the year are higher, lower, or the same as in the year-earlier period. Index numbers then are computed by subtracting the percentage of bankers that respond "lower" from the percentage that respond "higher" and adding 100. Hence, index values above 100 indicate higher average values than a year earlier; index values below 100 indicate the opposite condition.

Figure 2 charts the pattern of changes in the indexes for farm loan demand and fund avail-

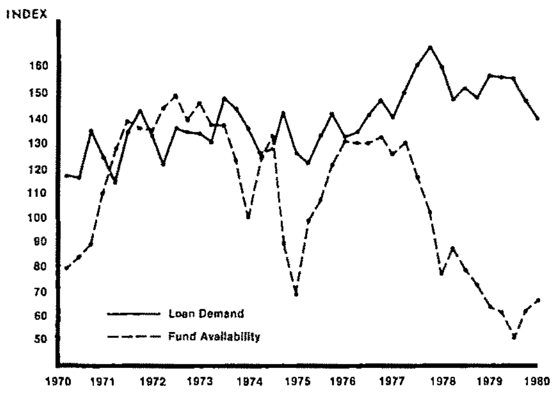

Figure 2. Loan demand and fund availability

ability for the 1970–1980 period. Since 1970, the index for farm loan demand ranged from a low of 114 in the first quarter of 1971 to a high of 169 in the third quarter of 1977. Hence, banks' observations of continued growth in farm loan demand are indicated by the index always remaining above 100. In contrast, the index of fund availability shows much variation with several movements around 100. Indeed, the later portion of the time period shows much disparity in the two indexes with fund availability reaching a decade low of 51 in the second quarter of 1979.

Table 2 shows several statistical measures for the quarterly series of index values for the period beginning in 1970 and extending through the first quarter of 1980. The coefficient of variation for the fund availability index is relatively high, especially in comparison with the coefficient for the loan demand index. This high variability in fund availability implies high variability of farmers' credit reserves. It thus adds to variance of farmers' borrowing costs through the liquidity premium portion of the cost of borrowing. In turn, higher variance of borrowing costs adds to farmers' portfolio risk.

Farmers' credit risks are further influenced by the correlation between changes in loan demand and fund availability, although the relationship depends upon the cause of change in farm loan demand. Suppose that strong loan demand primarily is attributed to favorable farm income expectations. Then, using the covariance relationship in equation (4b) and recalling that the cost of borrowing and changes in credit reserves are inversely related, the lower the correlation between fund availability and loan demand, the smaller is the resulting portfolio risk. The condition implies that farmers' costs of borrowing are high when loan demands resulting from favorable income are high. In contrast, if strong loan demand results from farmers' needs for loan extensions, loan carryovers, or other liquidity purposes, then lower correlations between fund availability and loan demand will add to portfolio risk. Credit reserves would be smaller when liquidity needs are greater.

Results in table 2 show that indexes for farmers' loan demand and banks' fund availability have a covariance of −63.29 and a correlation coefficient of −.16. This low correlation could imply a stabilizing effect on farmers' portfolio risk, which offsets in part the risk added by variance of fund availability. However, the combined effects of several factors, including both business growth and liquidity needs, likely influenced farmers' loan demands over this time period (Federal Reserve Bank of Chicago). Hence, further study is needed of how factors influencing loan de-

Table 2. Measures of Credit Conditions at Seventh Federal Reserve District, Agricultural Banks, 1970–80

Index	Mean	Standard Deviation	Coefficient of Variation	Fund Availability Covariance	Fund Availability Correlation
Loan demand	137.73	13.48	.098	−62.39	−.16
Fund availability	107.24	29.41	.274		
Banks with loan-to-deposit ratio above desired level	105.59	24.80	.235	690.52	.95
Average loan-to-deposit ratio	58.24	4.43	.076	−104.84	−.80

mand are related to fund availability and farmers' risks.

Other evidence about fund availability is shown by relationships between the index for fund availability, the index of bank preferences for loan-deposit ratios, and actual loan-deposit ratios. Loan-deposit ratios are considered a general indicator of bank liquidity. While not shown in figure 2, the index of banks' preferences for lower loan-deposit ratios closely follows the pattern of the fund availability index; moreover, the correlation coefficient between these two indexes for the 1970–1980 period is .95. Hence, the loan-deposit preference index may serve as an alternative indicator of fund availability; fund availability is low when banks prefer lower loan-deposit ratios. Moreover, banks' actual loan-deposit ratios also show a close relationship with fund availability, although the relationship is inverse, as reflected in a correlation coefficient of −.80. Thus, the index for fund availability is low (high) when the actual loan-deposit ratio is high (low).

An important feature of these survey responses is that the bankers' observations likely are closely related to their expectations about future credit conditions. These expectations presumably are used in managing bank portfolios and making credit decisions. However, it is not clear whether the observations on loan demand might reflect transfers of farm customers to other lenders, or whether observations on fund availability indeed are independent of changes in loan demands. Hence, several sources of bias may influence the banks' survey responses.

Concluding Comments

Concepts and empirical results reported here have shown that credit reserves, valued in part for their role in risk aspects of financial management, are themselves subject to risk. Therefore credit risk also must be accounted for in farmers' total portfolio risk, and in analysis of risk and liquidity management. Indeed, if credit becomes too volatile, it loses value as a source of liquidity, thereby forcing farmers to seek other more costly sources.

The practical implications for risk management largely are empirical ones that depend on characteristics of specific farm situations. However, some general guidelines arise from this analysis. As an example, portfolio analyses earlier in the paper showed that the addition of risk measures for credit generally will lead to lower use of debt by farmers, although in selected circumstances relatively high covariances between borrowing costs and asset returns could warrant higher use of debt. Similarly, very high covariance could warrant increased debt in response to increase in business risk. In practice, these responses are unlikely since responses of surveyed lenders indicated a strongly positive relationship between credit and level of farm income, implying a negative relationship between borrowing costs and levels of income. Hence, greater business risk is associated with higher borrowing cost, thus favoring lower leverage. Moreover, relatively high variability of fund availability from rural banks adds to farmers' credit risk, thus favoring lower leverage.

The differences in lenders' responses between operating and capital credit are important too. While operating credit appears more stable than capital credit, reduction in availability of operating credit may trigger other adjustments to sustain the farm's operations. Examples might include reductions in operating inputs, changes in enterprises, sales of capital assets, or changes in marketing plans (storage, hedging) that reduce needs for inventory financing. Alternatively, farmers might seek other sources of financing, refinancing into longer-term loans, or access to government loan programs. Similar responses might occur for fund availability problems at rural banks.

Higher variation in availability of capital credit shows that financing capacity for firm growth is strongly linked to business performance, at least in the preceding year. Moreover, restricting capital credit is a favored means of financial control for lenders. Implications for macroinvestment analysis also are evident in the tendency for changes in credit availability rather than changes in interest rates, especially for rural banks, to serve as key methods of financially constraining farm investment and growth.

Clearly there is need for further empirical and conceptual research on measuring credit risks and on evaluating appropriate responses by farmers, by lenders, and by public policy. The results obtained here are based on credit measures with rather limited geographic scope and small sample size; however, it would be surprising to find that results differ much for other locations, other farm types, other lend-

ers, or larger samples. These measures also focused on lenders' nonprice responses to farm risks and to financial market forces. More study is needed of interest rate responses, especially to financial market forces. Rural banks, for example, are expected to become more price responsive in the future, although time and experience are needed to verify these expectations.

Determinants of Public Services Provision in Rural Communities: Evidence from Voting on Hospital Referenda

Rodney D. Fort and Jon B. Christianson

There has been considerable recent research regarding the determinants of consumer demand for collectively provided goods, but relatively little of this research has focused on rural areas or issues that are particularly important to rural residents. In this paper, a public choice analytical framework is adopted to analyze voting behavior on rural hospital referenda. The results of the analysis aid in understanding support given by rural residents to low occupancy, rural hospitals and in predicting opposition to public sector efforts to close such facilities.

Key words: public services, referenda, rural hospitals, voting.

The purpose of this paper is to identify factors influencing support for rural hospitals as revealed through voting outcomes on hospital referenda. In the past, several researchers have noted the relative lack of empirical research based on well-developed theoretical models of community service provision in rural areas (Day, Jones and Gessaman, Eddleman, Brunn and Jones, Jones and Murdock, Dunn and Doeksen). In particular it has been observed that little is known regarding rural consumer preferences for collectively provided goods and services (Jones and Gessaman, p. 942; Eddleman, p. 959; Brunn and Jones, p. 46; Vlasin, Libby, Shelton, p. 900; Jones and Murdock, p. 955; Freeman, p. 917) and the roles which institutional factors and special interest groups play in explaining observed levels of service provision (Jones and Gessaman, p. 937; Eddleman, pp. 959–60; Brunn and Jones, pp. 379; Vlasin, Libby, Shelton, p. 908; Dunn and Doeksen, p. 53). The analysis of voting patterns on referenda pertaining to rural public services has been identified as one potentially productive method for addressing these issues (Jones and Gessaman, p. 942; Vlasin, Libby, Shelton, p. 907; Freeman, p. 917).

In analyzing voting behavior on rural hospital referenda, the paper adopts the public choice analytical framework suggested in this journal by Ostrom and by Arnold. Central to the public choice approach is the incorporation of the individual consumer as an integral component in a theory of collectively provided services (Arnold, p. 860), as well as the explicit consideration of the impact of institutional design on collectively provided service levels (Ostrom, p. 849). Hence, the analysis addresses some of the shortcomings in the existing literature as cited above.

The paper is organized in four parts. First, a description is provided of hospital referenda and their policy importance. Then a theory of individual utility maximization in the presence of both private goods and collectively provided hospital capital is developed. This theory is placed within a specific institutional context that emphasizes the potential for special interest groups to influence the level of rural hospital referenda expenditures. Third, the modifications of the theory required for empirical application are described. In particular, the example of other authors is followed in adopting a "representative voter" approach to accommodate the aggregated nature of available socioeconomic data and secret ballot vot-

ing results. Hence, although grounded in a theory of individual behavior, the empirical interpretations pertain more generally to "community" support for rural hospitals (Deacon and Shapiro). Finally, an empirical analysis is conducted of voting behavior in rural hospital referenda as a function of the explanatory variables suggested by the theory, and the results of this analysis are interpreted.

Background

In accordance with the National Health Planning and Resource Development Act (1974), guidelines for health planning were issued by the Department of Health, Education, and Welfare in 1978. Among other recommendations, the guidelines suggest that a maximum of four hospital beds per thousand people and a minimum of an 80% occupancy rate for these beds are desirable for an efficient hospital system (Zwick). Rural hospitals typically exhibit occupancy rates considerably lower than the recommended 80% and therefore are regarded as inefficient because these low occupancy rates are believed to result in higher than necessary hospital costs. These costs presumably are reflected in charges, area insurance premiums, and state and federal Medicaid and Medicare reimbursements for rural hospital services, thereby shifting some of the burden imposed by the excess capacity to taxpayers and insurance purchasers outside of rural areas. One implication of the guidelines is that these collective costs could be reduced through reductions in rural hospital capacity so long as the reductions did not significantly impair access to acute care for rural residents.

In the policy debate surrounding the guidelines, rural residents have strongly supported low occupancy rural hospitals, citing the importance of the facilities to local economies and their usefulness in attracting physicians and providing emergency medical services (Zwick). Furthermore, rural residents point out that they often subsidize hospital operating losses with local tax revenues, thereby accepting a portion of the social costs which might result from the inefficient use of resources implied by low occupancy rates. The analysis below attempts to illuminate this policy debate by identifying the important determinants of support for rural hospitals using a well-defined economic framework. Voting outcomes on hospital referenda in rural areas are particularly well suited as empirical indicators of support within such a framework. Pommerehne and Schneider argue that the incentive for voters to make informed decisions is greatest in referenda elections because these elections address one well-defined issue. Typically, the debates prior to the vote on a hospital referenda are vigorous, and the ballot choices are clearly stated. Hence there is relatively little voter uncertainty about tax effects and total expenditures. This makes the personal benefit-cost calculus of voters less complicated than for other types of elections and reduces the incentives for voters to be "rationally ignorant." Therefore, by relating referenda voting outcomes to characteristics of voting populations and of the referenda themselves, it is possible to identify important determinants of support for hospitals in rural areas.

The typical rural hospital referendum process is initiated when the desire for a facility is made known to elected officials by a local "health contingency" composed of physicians, health care administrators, and concerned elements of the general population. In the abstract, Romer and Rosenthal (1978, 1979a, b) refer to this group of influential citizens as the "setter." The hypothesized goal of the setter is public expenditure maximization. Based primarily on the setter's advice, the policy maker then proposes the level of the referendum. The referendum usually takes one of three forms: funds for building a new hospital where none existed previously, funds for building a hospital to replace an existing facility, or funds for remodeling or expanding an existing hospital. Typically, the referendum is characterized by the health contingency as an "all-or-nothing" proposition. For the first category, a new hospital, the threat is that physicians will leave the rural community (or will not be attracted to the area) unless the facility is built. In the remaining cases, the threat is that physicians will leave and/or that Medicare/Medicaid accreditation will be lost, forcing the facility to close, unless the referendum is passed. Thus, voters are faced with an apparent choice between the tax expenditure associated with referendum passage or alteration of the current level of hospital services should the referendum fail to pass.

Model

Assume that an individual *i*, confronted with a hospital referendum voting decision, pos-

sesses a well-behaved utility function incorporating (for simplicity of exposition) only collectively provided hospital services g, and a privately provided good x:

$$(1) \qquad u^i = u(g,x).$$

Adopting the approach of Mikesell and Blair in their analysis of voting on school referenda, hospital services are assumed to require capital (w) and labor (l) inputs,

$$(2) \qquad g = g(w,l).$$

It is assumed that a unique level of labor is associated with each level of collectively provided hospital capital. This assumption is reasonable in light of Medicare/Medicaid regulations requiring specific numbers and types of personnel per hospital bed. Hospital services then can be treated as a variable affected only by adjustments in the level of hospital capital:

$$(1') \qquad u^i = u(g(w),x).$$

In this simple, two-good world, the individual budget constraint is

$$(3) \qquad I^i = px^i + rv^i$$

where I^i is income of the ith individual, p is price of one unit of the privately provided good, x^i is units of the privately provided good consumed by the ith individual, r is mill rate levied to cover the cost of collectively provided hospital capital, and v^i is assessed value of taxable property possessed by the ith individual.

The mill rate is assumed to be determined by the collective taxing authority from the balanced budget constraint

$$(4) \qquad h[g(w)] = G[g(w), I^c] + rV,$$

where $h[g(w)]$ is the cost of a given level of collectively provided hospital capital, V represents the total assessed value of all community taxable property, and I^c is the community income level. The specification of G in equation (4) allows for intergovernmental grants. Historically, the level of rural hospital capital stock has been influenced by federal grants under the Hill-Burton Program. Hill-Burton grants were related positively to the amount of proposed spending for hospital construction and negatively to the community income level (Lave and Lave). Solving (4) for the mill rate, r, substituting into (3), and rearranging terms yields the consumer's reduced private-social budget constraint,

$$(5) \qquad I^i = px^i + \frac{v^i}{V}\{h[g(w)] - G[g(w), I^c]\}.$$

The highest attainable level of individual utility occurs where (1′) is maximized subject to constraint (5). It can be demonstrated that optimal consumer behavior results in the allocation of expenditure so that the marginal utility per dollar spent on x and $g(w)$ is equal. (The mathematical development is available in mimeographed form from the authors.) Furthermore, in equilibrium the consumer's valuation of the additional utility from a change in hospital capital stock just equals the consumer's additional cost resulting from that change. However, the individual is not free to attain a personal optimum level of $g(w)$ because the level of hospital capital is the result of a nonincremental, collective decision. Hence, a theory that unifies the individual optimization strategy and the institution of voting is required.

Assuming that the constraint in equation (5) is satisfied, the optimal level of private consumption can be expressed in terms of price, disposable income, and a predetermined level of collectively provided hospital capital. The highest attainable level of utility for individual i can be written as

$$(6) \qquad \max u^i = U_k{}^i(p_k, g(w_k), I_k{}^i - \frac{v^i}{V}\{h[g(w)] - G[g(w), I^c]_k\}).$$

A change in public policy toward provision of hospital capital would affect those variables with the k subscript. (Since v^i/V is in part choice-determined, its inclusion as a parametric variable on the right-hand side of (6) is not strictly valid. However, this does not alter the essential model results.) A referendum confronts the voter with a choice between two alternative outcomes. Let $k = 0$ denote the outcome if the referendum fails to pass, and let $k = 1$ denote the outcome if the referendum does pass. The highest attainable utility levels associated with each outcome are $U_0{}^i$ and $U_1{}^i$, respectively:

$$(7) \qquad U_0{}^i = U^i[p_0, g(w_0), I_0{}^i - \frac{v^i}{V}(h - G)_0],$$

$$(8) \qquad U_1{}^i = U^i[p_1, g(w_1), I_1{}^i - \frac{v^i}{V}(h - G)_1].$$

The voting rule consistent with utility maximization is vote YES if $U_1{}^i > U_0{}^i$, otherwise

vote NO. This voting rule abstracts from the case where $U_1^i = U_0^i$. With equal alternative utility levels, it is possible that the voter may abstain; however, the voter's presence in the booth is taken as evidence that this condition is not in force.

Data and Empirical Modifications

Explanatory variables expected to influence the individual's voting decision can be identified conveniently in terms of the difference in potential utilities under referendum passage and referendum failure (Deacon and Shapiro). This difference in potential can be written in "change notation" as

$$(9)\quad U_1^i - U_0^i = \Delta U^i\Big(\Delta p, g(\Delta w),\ \Delta I^i - \frac{v^i}{V}\,\Delta\{h[g(w)] - G[g(w), I^c]\}\Big),$$

where Δp, Δw, ΔI^i, and $\frac{v^i}{V}\ \Delta\ (h - G)$ represent differences in private goods prices, hospital capital, income, and tax bill.

An empirical test of the model was developed based on voting results in rural hospital referenda in ten states (Colorado, Idaho, Kansas, Montana, Nebraska, Nevada, North Dakota, South Dakota, Utah, Wyoming) during the years 1946–1978. Through an initial survey of 542 county clerks in August 1979, 152 health care referenda were discovered. Of these referenda, sixty-nine elections relating only to hospitals were chosen for analysis. A subsequent, more detailed, survey produced complete data on voting outcomes and referenda characteristics in fifty-five cases, including seven elections involving new hospitals where none existed previously, eighteen elections involving additions to existing hospitals, and thirty elections involving replacement hospitals.

The categories of explanatory variables selected for empirical analysis included (*a*) the level of hospital capital that would prevail under passage of the referendum, w_1; (*b*) the level of capital associated with referendum failure, w_0; (*c*) income, I^i; (*d*) expected income changes due to passage or failure of the referendum, ΔI^c; (*e*) the prices of collectively provided hospital capital to the representative resident, v^i/V; and (*f*) intergovernmental grants. Unfortunately, data limitations required the use of proxy measures in the empirical estimation of the model. For instance, the exact nature of the capital stock which would result from a referendum passage, w_1, would be uncertain from the voter's perspective. Therefore a proxy variable was defined for w_1 that was simply the referendum dollars which would be spent per county resident. This approach also was adopted by Mikesell and Blair (p. 405) and Borcherding and Deacon (p. 893). In explaining use of this proxy in analysis of school referenda, Mikesell and Blair argued that "school district community service expenditure per pupil . . . introduces visibility of both latent and manifest functions provided by the school plant and facilities. Higher levels of these expenditures will increase individual perception of the public output from school buildings and, hence, the percentage of voters favoring a bond issue" (p. 405). Similar expectations were held with respect to the influence of expenditure per capita in voting on rural hospital referenda.

Proxy measures also were required for the level of hospital services the voter expected to prevail if the referendum failed (w_0). Two alternative descriptions of hospital capital stock levels under referendum failure (or "reversion" levels of capital stock) were compared for analysis of cases where there were existing facilities. If the voter expected to lose the existing facility in the event of referendum failure, then the voter-anticipated available hospital capital was assumed equal to that level associated with the next best alternative, defined as the facility nearest the one threatened with closure. (This also was adopted as the reversion level in referenda for new facilities, with the alternative defined as the nearest facility to the county seat.) On the other hand, if the voter did not believe the threat of facility closure, then the set of characteristics describing the present facility (the "status quo") was assumed to describe the relevant reversion level expected by the voter.

The variables chosen to reflect capital stock levels under each assumption were (*a*) the size of the hospital, *S*, measured by the number of beds; (*b*) the percentage of occupancy rate during the year of the election, 0, indicating the average availability of hospital capital; (*c*) the age of the building, *a*, a proxy for the condition of the structure itself; and (*d*) the road distance from the existing facility or the county seat to the nearest alternative, *D*, indicating response time and travel costs associated with utilization of the capital stock.

Because the referenda analyzed in this study involved changes in the property tax rate, the perceived cost of added services depended on the assessed value of an individual's taxable property. When

$$(\frac{v^i}{V})_A > (\frac{v^i}{V})_B,$$

and the A and B subscripts indicate different counties, the implication is that desired levels of collective hospital capital would be greater in county B than in county A. The proportional tax cost for the representative individual in each county was approximated by dividing the median county housing value by the total county taxable property value. (The conditions under which this empirical measure of tax impact can be interpreted as reflecting different desired levels of spending are described in detail by Barr and Davis [p. 152] and appear valid for the theoretical model developed in this paper).

The model also suggests that intergovernmental grants through the Hill-Burton Program would affect the voter's decision. Data were available on (*a*) the expenditures specified in the sample referenda and (*b*) the hospitals in the sample receiving Hill-Burton funds. Unfortunately, it was not possible to ascertain whether expenditures specified in the referenda covered the difference between total project cost and Hill-Burton monies. Hence, a precise estimate of the effect of Hill-Burton money on net county cost $\{h[g(w)] - G[g(w), I^c]\}$ in equation (9) was unobtainable. However, data were available to construct binary variables defined as (*a*) Hill-Burton funding within eight years prior to the election and (*b*) within eight years after the election. It was hypothesized that the presence of Hill-Burton funds would have a positive effect on the probability of a yes vote, *ceteris paribus,* because the county would not actually receive the approved funds unless the balance of the total cost were covered. The omitted category was "no Hill-Burton funding" within eight years of the election.

Income variables suggested by the model include the income of the representative voter at the time of the referendum, I^i, and expected changes in income under passage and failure of the referendum ΔI^i. While I^i can be measured by median household income, perceived changes in income are unobservable. Past studies have addressed this problem by identifying groups within the population that could be expected a priori to experience changes in income due to changes in hospital output. The proxies used for empirical analysis were (*a*) the percentage of the county population which was employed full time in the existing facility at the time of the referendum and (*b*) the percentage of the county population which was employed in retail and wholesale establishments. The latter was adopted as a proxy for a group in the community which would be affected by changes in hospital expenditures and the expenditures of hospital visitors.

It also was expected that aggregate voting results would be related to the relative size of groups of potentially high demanders in the referenda counties (Deacon and Shapiro). Consequently, the following variables were introduced: the percentage of the county population over sixty-five years of age and the birth rate per thousand population in the county.

In addition to the explanatory variables described above, two sets of variables were included in the empirical analysis as controls. First, the year of the referendum was used to control for institutional changes over time, such as the introduction of Medicare and Medicaid reimbursements. Second, two binary variables were utilized to differentiate among the types of issues covered by the referenda: new hospitals where none previously existed, replacement of existing hospitals, and additions to existing hospitals.

In summary, a framework for estimating aggregate community responses to proposed changes in hospital capital levels was developed in a previous section of the paper. While secret ballot voting procedures preclude estimation of any particular individual's demand, the existence of known voting outcomes for small geographic areas does allow inferences to be made about community preferences from aggregate behavior, subject to the following types of assumptions. First, because voting outcome data are available only in an aggregate form, it must be assumed that summary, and some cases proxy, values for explanatory variables can be used in place of individual values. (All monetary variables were expressed in real terms using 1967 dollars. A complete description of data and sources is available from the authors upon request.) Second, since actual voting outcomes are to be explained and values used for some of the explanatory variables pertained to the general population (not just voters), it must be assumed that the characteristics of voters coin-

cide with the characteristics of the general population. Finally, it was assumed that no changes in the prices of private goods were anticipated by voters because of changes in hospital capital stock.

Results

Three basic linear models were estimated:

(10) $Y = \alpha + \beta x + \epsilon$,
(11) $Y = \alpha' + \beta' x + \theta s + \epsilon$, and
(12) $Y = \alpha' + \beta' x + \gamma t + \epsilon'$,

where s is a set of characteristics describing the alternative reversion level of capital stock, t is a set of characteristics describing the status quo reversion, $\mathbf{x}$ is a vector containing all other explanatory variables, Y is a variable representing voting behavior, ϵ is a normally behaved error term, and the α's, β's, θ's, and γ's are model parameters.

The logit model specification was adopted for estimation of equations (10–12). This specification assumes that the probability of voting yes for any individual is logistically distributed. (Pindyck and Rubinfeld, p. 247). In logarithmic form it reduces to

$$\log \frac{Pr(Y)}{[1 - Pr(Y)]} = \alpha + \beta \mathbf{X}, \tag{13}$$

where $Pr(Y)$ is the probability of a yes vote given the vector of explanatory variables, $\mathbf{X}$. With repeated sample observations for given values of the explanatory variables, $Pr(Y)$ can be approximated using the ratio of yes votes to total votes in a given election. Therefore, equation (13) becomes

$$\log \left(\frac{Y}{N}\right) = \alpha + \beta \mathbf{X}. \tag{14}$$

Cox (pp. 33–34) has demonstrated that an amended version of the model performs better for small sample data:

$$\log \left(\frac{Y + 1/2}{N + 1/2}\right) = \alpha + \beta \mathbf{X}. \tag{15}$$

Further, since the specification in equation (15) is characteristically heteroskedastic (Kmenta, p. 426) weighted least squares is appropriate. The weights applied to both sides of (15) in estimation were the inverses of the square roots of the variances of the dependent variable (Intriligator, pp. 165–173). These weights attach greater importance to referenda with a large number of voters as well as to referenda where the voting outcome is close.

Table 1 presents the results of estimating equations (10)–(12) using the weighted logit technique. Evidence concerning the explanatory power of the reversion capital stock levels is revealed in four ways. First, none of the characteristics chosen to represent either reversion level are significant individually at the 80% confidence level. In addition, an F-test reveals that these characteristics, taken together, do not contribute significantly to the explanation of the probability of a yes vote for either specification. Third, all capital stock characteristics taken together (i.e., all characteristics pertaining to both the alternative reversion and the status quo reversion combined) do not contribute significantly to the explanation of the probability of a yes vote. Finally, the F-value for the alternative reversion set of characteristics is significant at the 77.7% confidence level while the F-value for the status quo reversion set of characteristics is significant at the 76.8% confidence level. This small difference suggests that neither reversion specification is preferable on statistical grounds. (Given the small difference between these significance levels, the test statistic suggested by Pesaran [1974] was not computed.)

For equation (10), the basic model in table 1, the following results are consistent with a priori expectations (significance levels are in parentheses): (*a*) the probability of a yes vote decreases as the cost $\frac{v^i}{V}$ of collectively provided hospital capital to the representative voter increases (99%); (*b*) the greater the proportion of residents who stand to gain in terms of increased business interplay with the hospital and its visitors, the more probable is a yes vote (99%); (*c*) the probability of a yes vote increases if Hill-Burton funds were approved within eight years prior to the election relative to the omitted category, "no Hill-Burton funds" (80%); and (*d*) changing preferences and institutional arrangements over time have increased the probability of a yes vote (80%).

Two highly significant empirical results deserve special attention. First, referenda for replacement hospitals increase the probability of a yes vote relative to referenda for new hospitals where none existed previously (99%). Apparently, rural communities which have

experienced a local hospital are stronger supporters of hospital referenda than communities where no hospitals exist. Second, the probability of a yes vote is inversely related to levels of expenditure per capita (99%). This result is counter to expectations. The theoretical model hypothesized that voters made their decisions by comparing the utility levels associated with passage or failure of the referendum. Therefore any element of the referendum proposal that decreased utility was expected to have an adverse effect on the probability of a yes vote. The empirical result that higher relative expenditure per capita levels decreased the probability of a yes vote implies that if rural residents could have more expenditure per capita at the same price, they would not desire it. Possible explanation of this finding is that residents of rural counties are debt-averse.

At first glance, the significant negative coefficient on the expenditures per capita variable does not seem to conform with the fact that rural hospital elections pass with few exceptions. One explanation for this apparent inconsistency is based on the distribution of benefits and costs from the provision of rural hospital capital through debt financing. The empirical results suggest that voters involved in retail and wholesale trade are likely to be supporters of rural hospital referenda. This outcome is consistent with the hypothesis that this group of voters, and other groups like them, receive concentrated benefits from an increase in hospital capital. Conversely, the costs associated with an aversion to collective debt are likely to be diffused across all voters. It is expected that those voters who stand to gain substantially are more likely to vote than are other rural residents. Further, the goals of these potential gainers are in accordance with the hypothesized public expenditure maximization goal of the setter. Hence, to the extent that the untility positions of potentially decisive voting groups are enhanced, the setter can act to increase expenditure-per-capita levels and still be confident of referendum passage. The utility gains from concentrated benefits outweigh the utility losses generated by aversion to debt. It is important to note that while this explanation may be intuitively appealing, the aggregative nature of the voting data does not permit careful examination of whether such groups are actually decisive. It would be necessary to employ individual voting data to explore in detail the validity of explanations such as this.

The empirical results which are not significant also deserve brief discussion. The variable for median family income of the rep-

resentative voter is insignificant and its sign changes under the two reversion capital stock specifications. One explanation for this outcome is the existence of multicollinearity among the independent variables. Regression results indicate that 99.7% of the variation in income can be explained by variation in the other independent variables. This problem also plagues the variables for hospital employment (R^2 = .958), percentage of the population over sixty-five (R^2 = .990), and birthrate (R^2 = .982). It is interesting to note that the coefficient for percentage of the population over sixty-five, which is nearly significant at the 80% level, has a negative sign. It was hypothesized that the elderly would be characteristically high demanders of hospital capital because of their greater than average demands for hospital services. An explanation for the opposite result may be that the elderly are averse to paying in the present for capital investments yielding long-run benefits which they may never capture. Alternatively, one could speculate that this group holds a relatively high proportion of the value of county taxable property and thus bears concentrated present costs if the referendum passes.

Conclusions

A theoretical model of voting on rural hospital referenda was developed and tested in this paper. The results have at least two interesting policy implications. First, it appears that increases in hospital capital expenditures per capita will not enhance the probability of referenda passage, all else remaining equal. This tends to indicate general dissatisfaction with the levels of public expenditures specified in the elections studied. However, the elections typically pass despite this dissatisfaction. One explanation of this outcome focuses on the distribution of benefits and costs from rural hospital provision, an explanation which cannot be explored empirically using the "representative voter" methodology employed in this paper.

A second conclusion of interest is that the characteristics of the hospital capital stock which would prevail if the referenda failed are not significant explanatory variables in the analysis. Yet, these variables commonly are offered in heuristic explanations of support for hospitals in rural areas. Instead, variables such as price and the relative importance of benefiting groups are statistically significant and consistent with a priori hypotheses. This suggests that support for rural hospitals and opposition to rural hospital closures will be strong in counties with relatively low personal property taxes and high concentrations of benefiting groups.

Estimating Farm-Level Input Demand and Wheat Supply in the Indian Punjab Using a Translog Profit Function

Surjit S. Sidhu and Carlos A. Baanante

Application of the translog profit function to farm-level data from Punjab, India, allowed a more disaggregated analysis of the farm production structure compared to the case of Cobb-Douglas formulation. The flexibility afforded by translog formulation permitted measurement of the different impacts that exogenous variables have within and across input demand and output supply functions. Policy-relevant elasticity estimates with respect to variable inputs and output prices, fixed inputs, a few soil-related "state-of-nature" variables measured by soil analysis, and education, which are usually considered constraints to farm production, were obtained, and two examples of policy applications were developed.

Key words: constraints, disaggregated analysis, farm production structure, flexibility, soil analysis, state of nature, translog profit function.

The econometric applications of the new production theory based on the duality relationship between production functions and variable profit functions represent a major step forward toward generating appropriate empirical estimates of agricultural supply and input demand functions which are crucial for applications of economic theory for agricultural development policy (Lau and Yotopoulos 1971, 1972; Yotopoulos and Lau; Yotopoulos, Lau, Lin; Sidhu; and Sidhu and Baanante). Furthermore, the development of flexible functional forms by Diewert (1971, 1973, 1974); Christensen, Jorgensen, and Lau; and Lau (1974, 1976) permits applications of the duality theory for a more disaggregated analysis of the production structure than has been possible by traditional approaches.[1] Thus, the need to aggregate heterogenous exogenous factors that are expected to differ in their impact within and across input demand and output supply functions is considerably reduced, and the use of an array of environmental factors is possible.

The purpose of this paper is to apply the normalized, restricted, translog profit function and the corresponding system of derived demand to the farm-level data for Mexican wheat varieties (MWV) from the Indian Punjab in order to generate policy-relevant empirical estimates for wheat supply and input demand functions. In addition to the usual types of variable and fixed inputs, a few soil-related, "state-of-nature" variables measured by actual soil analysis and education are included in this analysis.

The Translog Profit Function Model

In this section we first present a brief exposition of the concept of translog profit function and then develop some basic derivations to compute various input demand and output supply elasticities. The formulations constitute the basis for empirical implementation of the model in the next section.

A generalization of the normalized restricted translog profit function for a single output is given by Diewert (1974); Christensen, Jorgensen, and Lau:

Surjit S. Sidhu and Carlos A. Baanante are economists at the International Fertilizer Development Center, Muscle Shoals, Alabama.

[1] This is not to suggest that the traditional functional forms, for example, the Cobb-Douglas, are not appropriate for several other types of analyses, only that their use to study the details of structure of production is restrictive.

$$(1)\quad \ln \pi^* = \alpha_o + \sum_{i=1}^{n} \alpha_i \ln P^*_i + \tfrac{1}{2}\sum_{i=1}^{n}\sum_{h=1}^{n} \gamma_{ih}\ln P^*_i \ln P^*_h + \sum_{i=1}^{r}\sum_{k=1}^{m} \delta_{ik}\ln P^*_i \ln Z_k + \sum_{k=1}^{m} \beta_k \ln Z_k + \tfrac{1}{2}\sum_{k=1}^{m}\sum_{j=1}^{m} \phi_{kj}\ln Z_k \ln Z_j,$$

where $\gamma_{ih} = \gamma_{hi}$ for all h, i, and the function is homogenous of degree one in prices of all variable inputs and output. The definition of the variables and the notation used are as follows: π^* is the restricted profit—total revenue less total costs of variable inputs—normalized by P_y, the price of output; P^*_i is the price of variable input X_i, normalized by P_y, the price of output; Z_k is the kth fixed inputs; $i = h = 1, 2, 3, \ldots, n + k = j = 1, 2, 3, \ldots, m$; ln is the natural logarithm; and α_o, α_i, γ_{ih}, δ_{ik}, β_k, and ϕ_{kj} are the parameters.

Define $S_i \equiv P^*_i X_i/\pi^*$ as the ratio of variable expenditures for the ith input relative to restricted profit. Let $S_v \equiv V/\pi^*$ be the ratio of output supply (V) to normalized, restricted profit. Note that S_v is also equivalent to the ratio of the total value of output to restricted profit. Differentiating the translog profit function (1) with respect to $\ln P^*_i$ and $\ln P_y$ gives a system of variable input/profit ratio functions and an output supply/profit function (Diewert 1974; Christensen, Jorgensen, Lau). Because, however, the S_i and S_v sum to unity, the output supply equation can be ignored, and only the variable input equations and the translog profit equation (1) need be used for econometric estimation:

$$(2)\quad S_i = -\frac{P^*_i X_i}{\pi^*} = \frac{\partial \ln \pi^*}{\partial \ln P^*_i} = \alpha_i + \sum_{h=1}^{n} \gamma_{ih}\ln P^*_h + \sum_{k=1}^{m} \delta_{ik}\ln Z_k.$$

Profits and variable inputs are determined simultaneously. Under price-taking behavior of the farms, the normalized input prices and quantities (levels) of fixed factors are considered to be the exogenous variables.

Now, suppose that parameter estimates of equations (1) and (2) have been obtained. Then, the elasticities of variable input demands and output supply with respect to all exogenous variables evaluated at averages of the S_i and at given levels of variable input prices (for the case of fixed factors) are linear transformations of the parameter estimates of the profit function.[2]

Variable Input Demand Elasticities

From (2) the demand equation for the ith variable input can be written as

$$(3)\quad X_i = \frac{\pi}{P_i}\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(4)\quad \ln X_i = \ln \pi - \ln P_i + \ln\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right).$$

The own-price elasticity of demand (η_{ii}) for X_i then becomes

$$(5)\quad \eta_{ii} = \frac{\partial \ln X_i}{\partial \ln P_i} = \frac{\partial \ln \pi}{\partial \ln P_i} - 1 + \frac{\partial \ln}{\partial \ln P_i}\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(6)\quad \eta_{ii} = -S^*_i - 1 - \frac{\gamma_{ii}}{S^*_i},$$

where S^*_i is the simple average of S_i.

Similarly, from (4) the cross-price elasticity of demand (η_{ih}) for input i with respect to the price of the hth input can be obtained:

$$(7)\quad \eta_{ih} = \frac{\partial \ln X_i}{\partial \ln P_h} = \frac{\partial \ln \pi}{\partial \ln P_h} + \frac{\partial \ln}{\partial \ln P_h}\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(8)\quad \eta_{ih} = -S^*_h - \frac{\gamma_{ih}}{S^*_i},$$

where $i \neq h$.

The elasticity of demand for input i (η_{iy}) with respect to output price, P_y, can also be obtained from (4):

$$(9)\quad \eta_{iy} = \frac{\partial \ln X_i}{\partial \ln P_y} = \frac{\partial \ln \pi}{\partial \ln P_y} - \frac{\partial \ln P_i}{\partial \ln P_y} + \frac{\partial \ln}{\partial \ln P_y}\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(10)\quad \eta_{iy} = \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i}\cdot\frac{\partial \ln P_i}{\partial \ln P_y} - (-1) - \sum_{h=1}^{n} \frac{\gamma_{ih}}{S^*_i}(-1),$$

where $i = 1, \ldots, n$, $h = 1, \ldots, n$,

$$(11)\quad \eta_{iy} = \sum_{i=1}^{n} S^*_i + 1 + \sum_{h=1}^{n} \frac{\gamma_{ih}}{S^*_i}.$$

---

[2] In the case of the translog cost function, the input demand elasticities, evaluated at average input cost shares in total costs, are linear functions of parameters of the cost function (Binswanger, Baanante and Sidhu).

Finally, the elasticity of demand (η_{ik}) for input i with respect to the kth fixed factor Z_k is also obtained from (4):

$$(12)\quad \eta_{ik} = \frac{\partial \ln X_i}{\partial \ln Z_k} = \frac{\partial \ln \pi}{\partial \ln Z_k} - \frac{\partial \ln P_i}{\partial \ln Z_k} + \frac{\partial \ln}{\partial \ln Z_k}\left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(13)\quad \eta_{ik} = \sum_{i=1}^{n} \delta_{ik} \ln P_i + \beta_k - \frac{\delta_{ik}}{S^*_i}.$$

Output Supply Elasticities

Output supply elasticities with respect to output price, prices of variable inputs of production, and quantities of fixed factors, evaluated at averages of the S_i and at given levels of exogenous variables, can also be expressed as linear functions of parameters of the restricted profit function. From the duality theory (Lau and Yotopoulos 1972) the equation for output supply V can be written as

$$(14)\quad V = \pi + \sum_{i=1}^{n} P_i X_i.$$

The various supply elasticity estimates can be derived from this equation. Rewrite (14) with the help of (3) as follows:

$$(15)\quad V = \pi + \sum_{i=1}^{n} \pi \left(-\frac{\partial \ln \pi}{\partial \ln P_i}\right), \text{ or}$$

$$V = \pi\left(1 - \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(16)\quad \ln V = \ln \pi + \ln\left(1 - \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i}\right).$$

Then, the elasticity of supply (ϵ_{vi}) with respect to the price of the ith variable input is given by

$$(17)\quad \epsilon_{vi} = \frac{\partial \ln V}{\partial \ln P_i} = \frac{\partial \ln \pi}{\partial \ln P_i} + \frac{\partial \ln}{\partial \ln P_i}\left(1 - \sum_{h=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_h}\right),$$

where $i = h = 1, \ldots, n$.

And, for the translog profit function case this becomes

$$(18)\quad \epsilon_{vi} = -S^*_i - \sum_{h=1}^{n} \gamma_{hi} \Big/ \left(1 + \sum_{h=1}^{n} S^*_h\right).$$

The own-price elasticity of supply (ϵ_{vv}) is given by

$$(19)\quad \epsilon_{vv} = \frac{\partial \ln V}{\partial \ln P_y} = \frac{\partial \ln \pi}{\partial \ln P_y} + \frac{\partial \ln}{\partial \ln P_y}\left(1 - \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(20)\quad \epsilon_{vv} = \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i} \cdot \frac{\partial \ln P_i}{\partial \ln P_y} - \sum_{i=1}^{n} \sum_{h=1}^{n} \gamma_{ih} \Big/ \left(1 + \sum_{h=1}^{n} S^*_h\right),$$

$$(21)\quad \epsilon_{vv} = \sum_{i=1}^{n} S^*_i + \sum_{i=1}^{n} \sum_{h=1}^{n} \gamma_{ih} \Big/ \left(1 + \sum_{h=1}^{n} S^*_h\right).$$

And, finally, the elasticity of output supply (ϵ_{vk}) with respect to the fixed inputs Z_k is given by

$$(22)\quad \epsilon_{vk} = \frac{\partial \ln V}{\partial \ln Z_k} = \frac{\partial \ln \pi}{\partial \ln Z_k} + \frac{\partial \ln}{\partial \ln Z_k}\left(1 - \sum_{i=1}^{n} \frac{\partial \ln \pi}{\partial \ln P_i}\right),$$

$$(23)\quad \epsilon_{vk} = \sum_{i=1}^{n} \delta_{ik} \ln P_i + \beta_k - \sum_{i=1}^{n} \delta_{ik} \Big/ \left(1 + \sum_{h=1}^{n} S^*_h\right).$$

Empirical Estimation of the Model

The empirical application is now fairly straightforward. First, the model is specified in actual variables, and the variables are defined. Second, the parameters of the model are estimated using generalized least squares (GLS). Then the estimation results are presented and discussed.

Model Specification

From the general function (1), the normalized restricted translog profit function for the Indian Punjab farms producing Mexican wheat varieties (MWV) 1970–71 can be specified in actual variables as:[3]

[3] The basic farm-level data for this research pertain to Mexican wheat varieties (MWV) grown during the crop year 1970–71 in the Indian Punjab. These data were obtained from a stratified random sample spread over four different sites of the state and are thus quite representative of wheat production in the state. It should be noted that the second-order terms in the fixed inputs for which a priori technical and intuitive judgments did not support the existence of interaction are not included in the model. Out of a total of twenty-eight only sixteen second-order terms are included.

$$

where π^* is the restricted profit from wheat production per farm: total revenue less total costs of labor, chemical fertilizer, and animal power normalized by the price of wheat; P^*_L is the money wage rate of labor per hour normalized by the price of wheat. (The money wage rate is obtained by dividing the total labor expenditure for wheat production per farm by the quantity of labor including both family and hired labor.[4]); P^*_F is the money price per kilogram of fertilizer nutrients ($N + P_2O_5 + K_2O$) normalized by the price of wheat; and P^*_A is the money price of animal power (pair of oxen) per hour normalized by the price of wheat. (The money price is obtained by dividing the total animal power expenditure for wheat production per farm by the hours of use of animal power.)

The definitions of the seven fixed inputs Z_K, included in the specification of the profit function, are as follows: Z_1 is the quantity of capital equipment and machinery used for wheat production per farm measured as rupees of annualized flow cost of total expenditures and investments on these inputs (An interest rate of 10% is used to determine the annuities.); Z_2 is the land input (land) measured as hectares of wheat grown per farm; Z_3 is the soil (pH) of the farmland under wheat production (measured as a deviation of the average—over soil samples per farm—soil pH value from an "optimum" of 6.50); Z_4 is the soil organic carbon content of land under wheat production measured as percentage (a measure of soil organic matter); Z_5 is the available P_2O_5 and K_2O (P + K) in the soil (land under wheat production) measured in pounds per acre; Z_6 is the average number of years of schooling per family member (over 13 years of age) of the farm household; and Z_7 is the area-weighted average number of irrigations per hectare applied to wheat crop.

The parameters α_o, α, γ, δ, β, and ϕ are to be estimated and subscripts L, F, and A stand for the variable inputs of production labor, chemical fertilizer, and animal power, respectively.

Following the development of (2), the S_i functions for labor, chemical fertilizer, and animal power are obtained by differentiating the normalized restricted translog profit function (24) as follows:

$$
(25)\quad -\frac{P^*_L \cdot X_L}{\pi^*} = \alpha_L + \gamma_{LL} \ln P^*_L + \gamma_{LF} \ln P^*_F + \gamma_{LA} \ln P^*_A + \sum_{k=1}^{7} \delta_{LK} \ln Z_K,
$$

$$
(26)\quad -\frac{P^*_F \cdot X_F}{\pi^*} = \alpha_F + \gamma_{FF} \ln P^*_F + \gamma_{FL} \ln P^*_L + \gamma_{FA} \ln P^*_A + \sum_{k=1}^{n} \delta_{FK} \ln Z_K,
$$

$$
(27)\quad -\frac{P^*_A \cdot X_A}{\pi^*} = \alpha_A + \gamma_{AA} \ln P^*_A + \gamma_{AL} \ln P^*_L + \gamma_{AF} \ln P^*_F + \sum_{k=1}^{n} \delta_{AK} \ln Z_K,
$$

where X_L, X_F, and X_A are the quantities of variable inputs of labor, chemical fertilizer, and animal power, respectively. Other variables, parameters, and symbols are as defined earlier.

The model consisting of the normalized restricted translog profit function (24) and the S_i functions (25), (26), and (27) is estimated

[4] The total labor expenditure per farm includes the imputed costs of family labor at the wage rate paid to permanent hired labor. Child and female labor is converted into man equivalents by treating two children (or women) equal to one man.

using the data pertaining to the MWV from the Indian Punjab.

For statistical specification additive errors with zero expectations and finite variance are assumed for each of the four equations of the model. The covariances of the errors of any two of the equations for the same farm may not be zero, but the covariances of the errors of any two equations corresponding to different farms are assumed to be identically zero. Under these assumptions, an asymptotically efficient method of estimation (Zellner) is used to estimate jointly the equations (24), (25), (26), and (27) by the application of restricted generalized least squares. In addition to the symmetry constraints ($\gamma_{LF} = \gamma_{FL}$, $\gamma_{LA} = \gamma_{AL}$, $\gamma_{FA} = \gamma_{AF}$), the linear parametric constraints required are also imposed across equations.

Empirical Results and Their Implications

Restricted parameter estimates of the normalized restricted translog profit function and S_i equations for labor, fertilizer, and animal power are presented in table 1. Before proceeding further, we report the results of two formal statistical tests. The first test is conducted for the validity of the symmetry and parametric constraints across profit and S_i equations. The null hypothesis is that parameters of the S_i equations (25), (26), and (27) are equal to the corresponding same parameters in equation (24) and that $\gamma_{FL} = \gamma_{LF}$, $\gamma_{AL} = \gamma_{LA}$ and $\gamma_{AF} = \gamma_{FA}$. This is a joint hypothesis on the validity of imposing thirty-three restrictions to estimate jointly equations (24), (25), (26), and (27). An F-test statistic with good asymptotic properties is conducted to test this hypothesis (Theil). The computed $F_{(33,213)}$ equals 1.344, and the critical $F_{0.05(33,213)}$ equals 1.52. Thus, the null hypothesis (validity of the constraints) cannot be rejected at the 0.05 level of significance. This implies, among other things, that the sample farms, on an average, maximize profits with respect to normalized prices of the variable inputs, thus supporting empirically the assumption of profit maximization.

The second statistical test is carried out to test for the Cobb-Douglas (C-D) hypothesis. It $F_{(43,246)}$ equals 3.758, and the critical $F_{0.01(43,246)}$ equals 1.45. Thus, the hypothesis is rejected, and the translog representation appears to be more suitable than the C-D for the data and model specification being analyzed. This, however, does not mean that for a different model specification and/or data set the C-D formulation could not be appropriate and analytically useful and convenient. The estimates presented in table 1 form the basis for deriving elasticity estimates for wheat supply and input demand for the variable inputs of labor, fertilizer, and animal power presented in table 2. These elasticity estimates are obtained by using equations (6), (8), (11), (13), (18), (21), and (23). As noted earlier, the elasticities are functions of variable input ratios, variable input prices, levels of fixed inputs, and the parameter estimates of the translog profit function presented in table 1. These elasticities are evaluated at simple averages of the S_i and at geometric means of the variable input prices and of levels of fixed inputs. With this assumption, the elasticity estimates become linear transformations of the parameter estimates of the translog profit function, and an asymptotic F-value can be computed to test for their significance by imposing linear constraints on the appropriate parameters of the model (Theil, Mann). These asymptotic F-values are presented in parentheses in table 2.

Estimates of wheat supply and variable input demand elasticities for labor, fertilizer, and animal power with respect to wheat price, variable input prices, and fixed inputs are valuable results in themselves, as they are a prerequisite and can be applied readily to assess the impact of a variety of micropolicy actions.

In table 2, the elasticity estimates derived from the parameters of the translog profit function are compared with those derived from the Cobb-Douglas function. In the C-D case, the impact across variable input demand functions of labor, fertilizer, and animal power of a given change in any of the exogenous variables is symmetric. This, as is well known, is due to the constant unitary elasticity of substitution among all input pairs in the case of C-D function. The impact of a similar change

[a] Using equations (6), (8), (11), (13), (18), (21), and (23), and simple averages of input S_i ratios. F-values in parentheses; $F_{0.10}(1, 246) = 2.71$; $F_{0.05}(1, 246) = 3.88$.
[b] Significant at 0.01 level.
[c] Significant at 0.05 level.
[d] Significant at 0.10 level.

Their influence, however, is not uniform (as in the C-D case) on labor, fertilizer, and animal power demand functions. Expansion in farm capital, in the form of implements and machinery, for example, decreases significantly the demand for animal power, contributes positively for wheat supply, but is not significant for labor and fertilizer demands. Expansion of irrigation increases demand only for farm labor and fertilizer but not for animal power. The influence of expansion in education of the farm family is quite important. It increases demand for all variable inputs but, more importantly, for fertilizer and animal power. It also influences wheat supply significantly. Exogenous increases in land quantities also increase wheat supply and demand for all variable inputs of production. But again, the impact is not uniform. All price effects are quite reasonable and in accord with the usual hypotheses. Nonsymmetric nature of their impact, contrary to the C-D case, is as expected and more natural.

As pointed out earlier, the inclusion of soil-related, "state-of-nature" variables is rather an uncommon practice in farm economic analysis. Of the three soil characteristics (soil pH, soil organic carbon, and soil [P + K]) included in the analysis, the soil pH appears to be the most important environmental variable. It has a strong negative influence on wheat supply. It also has a nontrivial negative influence on labor and fertilizer demands.

Two Examples

A variety of policy analyses are possible by using the estimates presented in tables 1 and 2. Because fertilizer is an important purchased input in modern agricultural production, in this section we construct two examples to study the impact on fertilizer demand of exogenously (policy) determined changes in soil pH, education, and irrigation.

Soil pH is measured as a deviation of the actual pH from an assumed "optimum" of 6.5. The geometric mean of the pH deviation (from 6.5) is 1.93. The geometric mean of fertilizer use per hectare, at the geometric mean of pH deviation of 1.93 or a pH of 6.5 + 1.93 = 8.43, is 105.62 kilograms (kg.). The elasticity of fertilizer demand with respect to soil pH is −0.465 (table 2). This elasticity can be used to estimate the profit-maximizing level of use of fertilizer (N + P + K) at various pH levels holding other fixed inputs and prices of variable inputs and wheat constant. A few such configurations are presented in table 3. Thus, if average pH decreases from 8.4 to 8.0, fertilizer use will increase from 105 kg. to 115 kg. of nutrients per hectare.[5] This result also can be used to adjust recommendations for fertilizer application for MWV in the Indian Punjab. For example, in soils with a pH of 8, fertilizer use recommendation should be 10% higher than in the case of soils with a pH of 8.4, holding other things constant. It should be noted that, in general, the farm soil analysis data are used to make fertilizer recommendations for targeted crop yields and not for determining profit-maximizing levels of fertilizer use (see Singh and Sharma). To the knowledge of the authors, this is the first attempt where information on soil analysis is included in a formal farm-level input demand model.

Table 3. The Influence of Soil pH on Fertilizer Use, MWV, the Indian Punjab, 1970–71

pH	Change of pH Deviation from Geometric Mean (%)	Profit-Maximizing Level of Fertilizer Use (N + P + K) kg./ha.
8.05	−20	115.44
8.24	−10	110.53
8.43	0	105.62
8.62	+10	100.71
8.81	+20	95.80

Second, in table 4 the impact of exogenously (policy) determined changes in soil pH, irrigation, and education is presented. Each one of them individually can be increased or decreased by 10%, holding the other two constant at their geometric mean levels, and the resulting impact on fertilizer use can be compared. Similarly, one could construct information to evaluate the impact of other combinations of policy changes.

[5] It is well known that the soils in the Indian Punjab have high pH levels. This result indicates that high pH levels are a constraint to expand the role of fertilizer in increasing wheat production in the state. If further investigations, including research on crops other than wheat, support this result, there may be need for serious consideration of strengthening the ongoing soil reclamation work to lower pH levels in the Indian Punjab soils. Also, the long-run tradeoff between the effects of lowering fertilizer prices through subsidies or lowering soil pH by reclamation programs should be investigated.

Table 4. Effects of Changes in Soil pH, Irrigation, and Education on the Average Level of Fertilizer (NPK) Use in the Indian Punjab, 1970–71

Mean and Changes	Soil pH	Irrigation (Number of Irrigations)	Education (Average Number of School Years)	Average Level of Fertilizer Used (kg. of NPK/ha.)
−10% Education	8.43	7.00	1.50	103.6
−10% Irrigation	8.43	6.3	1.66	97.9
+10% Soil pH deviation	8.62	7.00	1.66	100.7
Mean	8.43	7.00	1.66	105.6
−10% Soil pH deviation	8.24	7.00	1.66	110.5
+10% Irrigation	8.43	7.70	1.66	113.2
+10% Education	8.43	7.00	1.83	107.5

Note: Effects evaluated at the geometric mean of prices of variable inputs and wheat and quantities of other fixed inputs and by using elasticity estimates of fertilizer demand with respect to soil pH deviation from "optimum," irrigation, and education. Geometric means of the variables are (*a*) soil pH deviation from "optimum" (6.5) = 193, (*b*) number of irrigations = 7.00, and (*c*) average number of school years = 1.66.

Conclusions

In this paper, the parameters of a model based on the normalized restricted translog profit function and the derived system of demand equations for variable inputs were estimated with farm-level data for Mexican wheat varieties from the Indian Punjab. In addition to the variable inputs of labor, fertilizer, and animal power and the fixed inputs of land, physical capital, and irrigation water, a few soil-related, "state-of-nature" variables measured by actual soil analysis and education were included in the model. While the empirical results for the specification employed are plausible, they also demonstrate in this case a lack of support for the hypothesis of the Cobb-Douglas form of the profit function. Of particular importance is the result that the flexibility afforded by the translog formulation allowed the exogenous variables to produce different impacts across input demand functions of labor, fertilizer, and animal power. This is much more natural as compared to the symmetric impacts produced in the case of the Cobb-Douglas formulation.

The formulation allowed a considerably more disaggregated analysis of the farm production structure than has been possible in the past. The elasticity estimates for input demands and output supply include both the price elasticities and the elasticities with respect to several other variables that are usually considered as constraints on farm production. Thus, policy analyses which evaluate the impact of changes in single price or nonprice variables or combinations of them become available.

Nutritional Adaptations of Linear Programming for Planning Rural Development

Peter H. Calkins

Linear programming can help plan rural development if the income-maximization and least-cost diet models are integrated within the resource and management limitations of small-scale representative farms. Seven modifications adapt linear programming to subsistence households. Caveats in this context include risk, level of nutritional awareness, production scale, and result sensitivity. Through six model formulations for a representative Nepalese farm, linear programming identifies the most nutritious and profitable production patterns; trade-offs between nutrition and income; and the costs of constraints relating to levels of credit, market availability, and human capital development.

Key words: linear programming, Nepal, nutrition, rural development, subsistence farms.

The decade of the 1970s focused increasingly on holistic solutions to rural deprivation. The shibboleths of the day called for "integration," "appropriateness," and attention to the nutritional and income needs of those passed by in the biochemical revolution in crop production of the 1960s. With regard to human nutrition, linear programming has proven successful in planning least-cost menus for hospitals in developed nations (Balintfy, Stimson and Stimson, Hall). But the institutional setting of the hospital or school in a developed country is far different from the homestead of a subsistence farmer.

The farm family in a developing country must be both an efficient producer and an efficient consumer of food. If we assume the objective is to maximize the value of production subject to meeting minimal dietary requirements, a linear programming framework can be applied at the local, household level. The linear program must combine the least-cost diet model with the income maximization model and build in the resource and management limitations of small-scale farms in representative agroclimates.

Previous studies have furthered such research methodology (Mudahar, Singh, Smith, Andrews and Moore). In this paper, I first summarize specific modifications for applying linear programming to small-scale farms in subsistence economies, while pointing out the limitations of linear programming as a tool in this context. Then, I use several linear programming formulations to test the feasibility of, and measure the trade-offs between, income and nutritional objectives. Finally, I illustrate the use of linear programming to identify more nutritious, higher-income production patterns for a representative farm in the hill region of Nepal.

Modifications of Linear Programming for Application to Subsistence Farms

The nonmarket orientation of subsistence farms means that they face unique limitations in the acquisition and use of technology and the factors of production and that they cannot depend upon the market to supply their food needs. The type of linear programming model used to optimize production on a farm in a developed, capitalistic economy must be re-

Peter H. Calkins is an assistant professor, Department of Economics, Iowa State University.

The author is grateful to Michael Boehlje, Iowa State University, Victor E. Smith, Michigan State University, and two anonymous reviewers for reviewing an early draft of this paper, and to Daniel Sisler and Richard Boisvert, Cornell University, for their suggestions in formulating the conceptual framework.

structured so that realistic and beneficial farm plans may be extended to subsistence farms. Seven modifications were developed in a study of four representative farms in Nepal (Calkins), which would apply to most subsistence contexts.

First, in addition to production, feeding, milling, selling, and input purchase activities, activities that portray processing, storage, purchase and consumption of fresh or preserved foodstuffs must be included (table 1). These permit the family to retain foods for home consumption and to spread their intake of nutrients over the year. An appropriate loss in nutrients should be included to reflect the effects of cooking, drying, or fermentation. Whenever a commodity can be either sold or consumed by the household, the model must contain both selling and consumption activities so that the solution will determine the optimal quantities to be devoted to each use. Radishes and paddy rice in table 1 are examples.

Second, nutritional constraints representing the aggregate family demand for each nutrient in each season (e.g., monsoon protein, winter niacin) should be included in the rows of the matrix at greater than or equal to minimum levels. The example in this paper includes nine types of nutrient constraints in each of three seasons, yielding twenty-seven matrix rows in all. Required levels may be taken from the recommended daily intakes for various sex and age groups (FAO). For example, the average daily requirements for a prime-age, adult male were 2,625 calories, 48 milligrams (mg.) protein, 450 mg. calcium, 18 mg. iron, 1,500 mg. carotene, 9 mg. thiamine, 1.35 mg. riboflavin, 14.7 mg. niacin, and 30 mg. ascorbic acid. For protein requirements in particular, the weight of each family member should be multiplied by the factors implicit in the FAO computations for "seemingly well-nourished" individuals. In this paper, no attempt will be made to take account of the quality of protein consumed, though this may be included through nonlinear formulations (Smith). Aykroyd is a good source of information about caloric requirements: for major age-sex groups over the age of fifteen, he gives basic metabolic and energy expenditure totals for different types of work. Labor records must then be consulted to determine the percentage of sedentary, moderate (e.g., cooking, walking, and harvesting grain), and heavy (e.g., carrying loads, woodchopping, and plowing) work performed by each sex-age group. Adjustments for different basic metabolic needs due to temperature changes should also be reflected in the figures for seasonal caloric requirements.

Third, constraints may have to be added to reflect the tastes and preferences of the local population. Sweet potatoes may be a rich source of β-carotene, but if the family refuses to eat any more than ten kilograms per month of this food, a less than or equal to constraint should be included. Similarly, there are physiological barriers to eating too much of a given foodstuff; it would be unrealistic to hope that a

Table 1. Partial Linear Programming Matrix Adapted for Human Nutrition on Farms in Developing Countries

Grazing transfer			−								+	L

Note: "+" indicates a positive matrix element coefficient; "−" indicates a negative matrix element coefficient; blank indicates no entry.

family could depend upon garlic as its major source of protein, for example. Thus, the "optimal" solutions for meeting the consumption demands most efficiently will not necessarily provide acceptable diets for the family. These "structural and variety requirements" are noted by Balintfy.

Fourth, the maximand must be changed from the simple "net farm income" of the standard linear program to "net farm income over consumption." Because of the changes listed above, the maximand now reflects not just the gross value of produce less the cost of purchased inputs and operating capital, but also the retention of part or all of the produce for home consumption and/or the purchase of food from the market to meet nutritional requirements.

Fifth, special attention should be given to computing the supply and productivity of labor, the most abundant resource on most subsistence farms. Careful observation of common tasks performed by each member of the family yields a coefficient of comparative productivity, which should be multiplied by the total number of hours per day that person has available for agronomic and livestock production. Where livestock grazing is a significant activity on the farm, a grazing externality activity should also be included to reflect the labor saved by herding more animals. As each animal is added, average labor requirements per head in the farm plan are reduced by an appropriate amount in the months in which the animals are herded.

Sixth, because of the malnourishment or even death which may attend crop failure, land allocation constraints should be included in some formulations to reflect the traditional allocation of land to broad classes of crops, like grains and legumes, which has allowed the farmer's forebears to survive in the area. Land purchase or rental activities should be included only after careful consideration of local conditions.

Finally, traditional production techniques should be adhered to, at least in the initial formulation of the model. The use of chemical fertilizers, pesticides, and other improved technology may not be suitable to the subsistence farmer's resources, risk-bearing ability, or level of management.

Alternative Formulations

In developing a farm model for use in generating income and nutritional policy recommendations for a wide number of farms, the linear program should be systematically modified to determine the sensitivity of the optimal solution to different policy measures and goals of the farm operator. For instance, the prices included in the maximand row, and the type or level of constraint as indicated in the right-hand sides may be varied, as well as the type and number of activities included in the matrix. The following six formulations were used by the writer (Calkins):

(*a*) the simple short run (allowing for adjustments that can be made within two cropping seasons) with no nutritional constraints;

(*b*) the short run with nutritional constraints and unlimited use of the market to meet consumption demands, i.e., the family may purchase food from the market place and sell surplus production;

(*c*) the short run with nutritional constraints and marketing limited by a ceiling on capital borrowing—this formulation both highlights the trade-off between income and nutrition and induces home labor to be more productive, as there are limited funds to hire outside labor;

(*d*) the short run with nutritional constraints and no food buying—this formulation shows the trade-off between income and nutrition when all food consumed on the farm must also be produced there;

(*e*) the short run with nutritional constraints plus the assumption that 75% of acreage must be planted to cereal and leguminous crops—this formulation reflects the opportunity cost, if any, of traditional cropping patterns; and

(*f*) the long run, a period ten years hence, including projected price relationships and allowing for changes in levels of livestock and fruit tree production—this gives an idea of the ways in which the production of given commodities may become or remain profitable or nutritious over time, and why.

One caveat with regard to the use of linear programming is its inability to treat risk. By assuming perfect knowledge of market prices and yields—with no account of how each varies separately over time, or how they work together to produce variable total revenues—linear programming tends to predict optimal combinations which may in fact be risky. The best way to overcome this problem is to reformulate the model as a quadratic program with the variance in returns as the objective function to be minimized and a target income as a parameterized constraint. Unfortunately,

in developing countries adequate time-series data are not available, while cross-sectional variances would ignore interannual price patterns. The 75% acreage constraint to grain and legumes, whose yields are fairly stable, is an alternative (if mechanistic) way of reflecting risk aversion.

A second caveat regards the assumption that subsistence families are aware of and wish to optimize their nutritional statuses. Linear programming can only suggest what optimal changes in the diet might be. Therefore, the optimal results must be attended by nutritional extension programs before they can be fully realized.

A third caveat regards expanding acreages to activities currently engaged in on a small scale. Not only does the traditional problem of linearity distort the programming of biological systems; there is also the heroic assumption that measurements of planted area, inputs, and output from, say, three tomato plants are sufficiently accurate to reflect production conditions on a per hectare basis.

A fourth caveat is that programming results may be sensitive to slight variations in resource levels, prices used, and the choice of maximum or minimum consumption levels and area constraints. Two approaches may be taken to improve result applicability. The first is to make sure that the farm selected is as representative as possible of its group for policy purposes. The farm in this paper is one of four chosen on the basis of a survey of 600 households to represent discrete microclimates and resource levels. Case studies were used rather than synthetic composite farms because of the dangers inherent in averaging resource availabilities and other structural parameters. The second approach is to perform sensitivity analysis to determine the range over which the results are applicable to a given farm.

The six institutional formulations to be presented do allow policy analysts to identify barriers that prevent households from taking advantage of crop and livestock production combinations which could increase nutritional adequacy and improve income. Given the caveats noted, such an identification of barriers may be of greater prescriptive usefulness than specific behavioral recommendations to individual farm operators.

Programming Formulations

In this section of the paper, I will illustrate the use of linear programming to identify more nutritious, higher-income production patterns for a representative farm in the hill region of Nepal.

A Sample Farm from the Nepalese Hills

To exemplify each of the six formulations, let us consider Masino Tamang (assumed name), whose homestead lies at 1,992 meters in a temperate-zone village in Nepal (Calkins, pp. 124–74). Masino has a total of 0.1526 hectares of irrigated lowland, 0.2910 hectares of unirrigated upland, and the following brood animals: 1 cow, 2 milk buffaloes, 4 ewes, and 2 hens. He is 62 years old and lives with his 52-year-old wife, his two daughters of 13 and 11 years, and his son of 5 years.

The current nutrient balance for the family in the early and monsoon seasons is fairly good, with a 40% riboflavin shortfall the only deficiency in the former and 8% calcium and 14% riboflavin deficiencies in the latter. In the winter season of two months, five of nine nutritional elements are deficient: riboflavin (by 58%), β-carotene (48%), ascorbic acid (12%), niacin (11%), and calories (4%). Riboflavin deficiency, present in all three seasons, can result in dry skin, inflamed corneas, and general debility. Only this deficiency is serious, because β-carotene, which is consumed in excess in the other two seasons, can be stored in the body's fat for much longer than two months.

Current production patterns. The following are the percentages of available land grown to each commodity for each type of land in each season (early, monsoon, winter) under Masino's current cropping patterns:

Early Lowland (14 Nov.–14 June)	(%)
Wheat	8.3
Fallow	91.7
Monsoon Lowland (15 June-14 Nov.)	
Paddy	100
Early Upland (15 Feb.–14 Aug.)	
Maize	68.9
Potato	1.5
Soybeans	0.7
Green beans	0.9
Pumpkin	0.2
Yams	0.2
Chayote	0.4
Bitter gourd	0.4
Green amaranthus	0.5
Red amaranthus	0.5
Chili	0.1

Early Upland continued	(%)
Mustard	4.4
Taro	8.7
Permanent crops	12.6
Monsoon Upland (15 Aug.–14 Dec.)	
Millet	17.6
Monsoon potato	8.7
Soybean	0.7
Pumpkin	0.2
Yams	0.2
Radish	32.4
Rape	0.4
Chayote	0.4
Bitter gourd	0.4
Chili	0.1
Mustard	17.6
Taro	8.7
Permanent crops	12.6
Winter Upland (15 Dec.–14 Feb.)	
Chayote	0.4
Chili	0.1
Mustard	4.4
Rape	0.4
Taro	8.7
Permanent crops	12.6
Fallow	73.4
Permanent Crops	
Mango	2.6
Peach	8.7
Bamboo	1.3
Net Income	
Rupees (Rs.)	3,580

Net income represents the total market value, before consumption, of all livestock and agronomic production for the year, less the costs of hiring labor and bullocks. The main double-cropping patterns are wheat followed by paddy in the lowland and monsoon millet transplanted into a standing early maize crop in the upland, with various horticultural crops occupying upland for from one to three consecutive seasons. Paddy and wheat are traditionally the only crops grown in the lowland, because it is a full hour's walk to many lowland fields from Masino's homestead.

Formulation One: The Simple Short Run

The simple short-run formulation stipulates that (*a*) permanent crop acreages and livestock levels are fixed, (*b*) food buying and selling activities are allowed, (*c*) there are no changes in technology, (*d*) there is no limit to capital borrowing, and (*e*) Masino Tamang only wishes to maximize the sale value of his product after production costs have been deducted. The following optimal land-use pattern emerges from linear programming:

Early Lowland	(%)
Wheat	100
Monsoon Lowland	
Paddy	100
Early Upland	
Potato	88.7
Permanent Crops	11.3
Monsoon Upland	
Rape	88.7
Permanent Crops	11.3
Winter Upland	
Rape	88.7
Permanent Crops	11.3
Net Income	
Rupees (Rs.)	14,926

One hundred percent of available irrigated land should be devoted to the wheat-paddy rotation. On unirrigated upland, on the other hand, potato and rape greens should be grown at the maximum permissible level. As upland constitutes about two-thirds of all land on the farm, this result shows a significant shift from grain to horticultural predominance to maximize income.

Formulation Two: The Short-run Optimal Solution with Nutritional Constraints and Unlimited Borrowing

We now expand the matrix to include nutrient constraints, which are varied from 0% to 150% of suggested FAO levels to measure the impact on cropping patterns, hiring, selling, feeding, consumption practices, and the level of income. The unbroken line in figure 1 shows that income over consumption declines from Rs. (Rupees) 14,925 to Rs. 11,253, reflecting up to a Rs. 3,672 "grocery bill" for adding 150% of the family's requirements over the eat-nothing, simple short-run, optimal formulation.[1]

At the 100% level of nutritional adequacy, a Rs. 2,375 grocery bill is used to buy 972 kilograms (kg.) of soybeans, 218 kg. of radish, 35 kg. of yams, 153 kg. of pumpkins, 53 kg. of mustard greens, and 1.8 baskets of peaches to meet nine nutritional requirements in three seasons. Optimal cropping patterns, labor and

[1] The lines in figure 1 for formulations two and three resemble curves only because they connect program values from individual linear programming formulations. They are not to suggest that nonlinear programming was used.

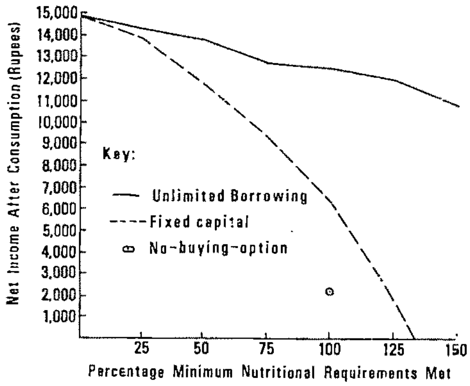

Figure 1. The trade-off between income and nutrition under unlimited borrowing, fixed capital, and no-buying-option formulations

bullock hiring. and livestock feeding activities do not change from those in formulation one. The only products previously sold but now retained are winter milk and early season peaches. This suggests that these are the cheapest sources of riboflavin and β-carotene, respectively, for these two seasons.

Formulation Three: The Short-run Optimal Solution with Nutritional Constraints and Fixed Capital

The cash with which Masino buys supplemental food for his family is limited. Formulation three parameterizes nutritional requirements subject to the constraint that Masino may borrow no more capital than 771 rupees needed in the simple income-maximizing solution. With each 25% increment in nutritional requirements, farm activities are forced in the direction of more nutritious but perhaps less profitable crops. The broken line in figure 1 represents this trade-off.

By the 100% level, the following pattern becomes optimal:

Early Lowland	(%)
Wheat	100
Monsoon Lowland	
Paddy	100
Early Upland	
Maize	38.8
Potato	49.9
Permanent crops	11.3
Monsoon Upland	
Millet	38.8
Radish	3.7
Rape	46.3
Permanent crops	11.3
Winter Upland	
Rape	46.3
Permanent crops	11.3
Fallow	32.7
Net Income Over Consumption	
Rs.	6,300

The most striking change that has occurred over formulation two is that early potato and monsoon rape production has been drastically reduced in favor of the maize-millet rotation. This shift reflects the fact that calories in all seasons (in addition to riboflavin) are nutritionally binding. Radish is also important enough to displace some of the rape on monsoon upland. This change occurs both because of the lack of capital to buy radishes and because with every hectare of radishes come a corresponding amount of nutrient-rich radish greens.

As to the trade-off between consumption and sales, paddy is earmarked for home use in the monsoon and winter, while millet, maize, and potatoes are grown to satisfy early season energy needs. All meat and fruit are now reserved for farm consumption. In addition, milk sales virtually disappear because of niacin and riboflavin needs, while millet supplies the necessary calcium in the early season. The only food which continues to be bought is soybeans, demonstrating what a valuable source of nutrients this grain legume is.

The restriction on capital not only means that farm output must be more nutritious, it also causes a shift from hired labor to labor-saving crops which can be grown by home labor. Seasonal redundancy of family labor is reduced.

Formulations one and two have demonstrated that the linear program can sort out the least-cost source of nutrients even when there is no effect upon the optimal production and input-hiring pattern, while formulation three has shown the ability of the model to develop production and consumption recommendations simultaneously.

Formulation Four: The Short-run Optimal Solution with Nutritional Constraints and No Food Buying

To reveal the trade-off between higher nutritional demands and on-farm production in its most extreme form, we may develop a forced self-sufficiency formulation, whereby Masino must meet 100% of his family's nutritional re-

quirements with no market purchase.[2] The following land-use pattern becomes optimal:

Early Lowland	(%)
Wheat	100
Monsoon Lowland	
Paddy	100
Early Upland	
Maize	53.4
Potato	35.3
Permanent crops	11.3
Monsoon Upland	
Millet	53.4
Radish	4.8
Rape	30.5
Permanent crops	11.3
Winter Upland	
Rape	30.5
Permanent crops	11.3
Fallow	58.2
Net Income over Consumption	
Rs.	2,092

This cropping pattern (and diet), represented by a circled point in figure 1, is much closer to traditional ones because of the predominant maize-millet rotation. The drawback is that income over consumption plummets from Rs. 12,479 to Rs. 2,092, indicating a strong trade-off between levels of income and nutrition if everything consumed on the farm must also be grown there.

As might be expected from current dietary deficiencies, the shadow prices under formulation four are highest for riboflavin in the early (Rs. 263 per mg.), monsoon (Rs. 66), and winter (Rs. 33) seasons, followed by monsoon and winter niacin (Rs. 1.1 and .06, respectively). Early monsoon and winter calories have shadow prices of Rs. .90, .60, and .30, respectively. That the above constraints are binding implies that cropping patterns in the no-buying-option formulation have had to be rearranged in favor of home-grown crops rich in these nutrients. Specifically, area grown to low-return maize and millet has been increased to relax the caloric and niacin constraints, while area grown to radish roots and greens has been increased to relax the riboflavin and niacin constraints.

[2] This stipulation means that one may generalize the results to all farmers of the temperate zone without fear of causing supply and demand distortions. One must, of course, assume that selling prices for produce remain at their present farmgate level and that such produce will be purchased from the farmer by middlemen for sale elsewhere.

Formulation Five: The Short-run Optimal Solution with Nutrition and Cropping Pattern Constraints

Formulation five posits that in meeting 100% of his nutritional demand with buying options and unlimited capital borrowing, Masino must follow the general practice of hill farmers: to devote about 75% of his upland to grain and legume crops. The following land-use system becomes optimal:

Early Lowland	(%)
Wheat	100
Monsoon Lowland	
Paddy	100
Early Upland	
Maize	68.9
Soybean	6.1
Potato	13.7
Permanent crops	11.3
Monsoon Upland	
Millet	68.9
Soybean	6.1
Rape	13.7
Permanent crops	11.3
Winter Upland	
Rape	13.7
Permanent crops	11.3
Fallow	75.0
Net Income over Consumption	
Rs.	2,370

There is a large opportunity cost associated with forcing maize-millet and soybean into the cropping pattern in accordance with traditional land use. This may be measured in terms of the difference in income over consumption (Rs. 10,109) between formulations two (Rs. 12,479) and five (Rs. 2,370) at the 100% level of nutrition.

Formulation Six: The Long Run

The final formulation allows livestock numbers and permanent crop areas to vary and employs projected input and output prices for the ensuing ten years. The solution for Masino's farm indicates that milk cow specialization within livestock, grain specialization on irrigated lowland, vegetable specialization on irrigated upland, and no fruit trees constitute the optimal use of land and other resources on temperate zone farms like Masino's in the longer term.

Sensitivity analysis of the prices of output and purchased inputs shows production patterns to be stable. However, varying purchased food prices induced great variation in optimal diet. These results suggest a possible policy of controlling relative prices to consumers in the marketplace.

Conclusion

The application of linear programming to a subsistence Nepalese farm has shown that large gains in income accrue from growing increased areas to potatoes, radishes, and rape on upland fields, depending upon the availability of capital and the flexibility of traditional cropping preferences. The cheapest sources of a full range of nutrients are also horticultural, including soybeans, radish, yam, pumpkin, mustard greens, and peaches. Only if the buying power of such commodities is reduced does maize-millet production for home consumption come into the optimal solution or products from the fixed activities, milk, meat, and fruit production figure in on-farm consumption.

Through different model formulations, linear programming can identify clearly the most nutritious and profitable production patterns. Moreover, formulations three through six reflect different types of institutional constraints involving, respectively, credit, market development, extension and education to alter traditional beliefs and strengthen human capital, and long-run price policies. These and other possible formulations permit the policy analyst to infer the direction of change in optimal patterns under various policy choices.

Microlevel studies of linear programming cannot solve nutritional and income problems in a vacuum, however, and must be supported by a commitment of research and extension resources. In Nepal, for example, horticultural crops are much more subject to price variability and marketing losses than grain crops. Government policies to improve marketing mechanisms and foster producer cooperatives would reduce the riskiness of horticultural production, which is now the main barrier that prevents farmers from realizing the benefits of growing these crops. Research should be geared to improving varieties of, and reducing pests in, those commodities with the greatest potential for increasing the nutrition and income levels of the rural population.

Notes

Income and Expenditure for Relatively More versus Relatively Less Nutritious Food over the Life Cycle

Laura Blanciforti, Richard Green, and Sylvia Lane

United States consumers have been accused of being nutritionally inefficient, having a poor quality diet, and often placing themselves at nutritional risk because of their poor choice of foods (U.S. Congress). Unfortunately, the controversy over the consumption of nutritious versus less nutritious or "junk" foods has generated heated discussion but relatively little economic research.

Numerous studies have been made of the income elasticities of food consumption (Burk 1962, Hymans and Shapiro), and Engel curves derived from econometric analysis of family budgets, primarily relating expenditures on food or another consumption good or commodity group to income levels of households, *ceteris paribus,* abound in the literature (Burk 1968, pp. 84, 215; Aitchison and Brown; Allen; Allen and Bowley; Champernowne; Cramer; Goreux; Hassan and Johnson 1977; Houthakker 1952, 1957; Prais and Houthakker; Phlips; and Tornquist). Adrian and Daniel in their 1976 article investigated the consumption of selected food nutrients in the United States using income and the life cycle stage as variables in their analysis, but they did not identify the foods which were the sources of the nutrients. Few researchers have examined the implications of and the differences in food expenditure patterns of households at various points in their lifetimes. And, more important, no research has been done on the expenditures on and income elasticities of the specific groups of food classified as relatively more nutritious and less nutritious components of diets.

The specific purposes of this analysis were to ascertain, using a general functional form, whether or not expenditures on foods classified as relatively more nutritious and less nutritious components of diets vary over the life cycle for U.S. households with different income levels, and to compare income elasticities for the various life cycle stages for all foods, relatively more and relatively less nutritious components of diets.

Description of Data

Cross-sectional data, obtained from the diary component of the second year of the 1972–1973 Consumer Expenditure Survey conducted by the Bureau of Labor Statistics, were used. Results of the 1973 Diary Survey were substantially better than those for the 1972 survey (Walsh). The sample from the 1973–74 portion of the survey totaled 10,514 observations (Carlson). The under $2,000 income group, 7.6% of the total sample and the over $35,000 group, 2% of the entire sample, were removed because their income was not recorded in actual dollar amounts. The exclusion of the over $35,000 group acted to offset partially the bias introduced by the exclusion of the under $2,000 group. Editing the data to remove observations incomplete for key variables results in 9,464 usable observations.

Income data collected was for each household's before-tax-income from all sources.[1] Expenditure data are recorded food-at-home expenditures for specific items. The data on food expenditures were grouped into three groups: total food at home, relatively more nutritious components of diets, and relatively less nutritious components of diets. The classification of foods into relatively more nutritious and less nutritious components of diets was based upon an analysis of the nutritive composition of the food items. The index of nutritional quality tables developed by Canolty of the Department of Nutrition of the University of California, Davis, were used for this purpose. To be termed "nutritious" (relatively more nutritious), a food had to contain percentages of the requirement for four or more nutrients equal to or greater than the proportion of the energy (calories) provided by that food, or the percentage required of two or more nutrients in twice the proportion to the energy contribution for that food (see table 1). This definition of nutritious is a recommended definition consistent with results from a 1976 study by the Society for Nutri-

[1] It is well known that the income variable as reported in household survey data has several deficiencies as an argument for Engel Curve estimation. For further explanation of this problem, see Brown and Deaton, p. 1172, and Hassan and Johnson 1976, pp. 5–6.

Table 1. Relatively More Nutritious and Less Nutritious Foods

Relatively More Nutritious Foods	Relatively Less Nutritious Foods
Cereals, flour, rice, pasta	Fresh cakes and cupcakes
Bread, biscuits, rolls, muffins	Cookies
	Crackers
Meats, poultry, fish and eggs (except bacon and frankfurters)	Sweet rolls, coffecakes, doughnuts
	Frozen and refrigerated bakery products, pies, tarts, turnovers
Dairy products (except ice cream and related products)	Bacon
	Frankfurters
Fruits and vegetables (except apples)	Ice cream and related products
Margarine[a]	Apples
Peanut butter	Sugar, candy, chewing gum and other sweets
Other prepared foods (except other condiments)	Other fats, oils and salad dressings
	Nondairy substitutes
	Nonalcoholic beverages
	Other condiments

[a] Butter is included in dairy products.

tion Education conducted for the Federal Trade Commission (Society for Nutrition Education).[2] The eight key nutrients used in the analysis were folacin, vitamin B-6, pantothenic acid, magnesium, vitamin A, calcium, iron, and vitamin E.[3]

Data for all households and the households stratified according to life cycle stages were used in the analysis. Since cross-sectional data are used the life cycle stages depict different families at each stage rather than a cohort of families moving through different stages. Life cycle stages in this analysis only provide a classification scheme.

The life cycle stages were:

Life cycle stage 0: all not included in groups one through six, i.e., single men, single women, etc.

Life cycle stage 1: no children are present and the housewife is 40 years of age or less.

Life cycle stage 2: average age of children is less than six years.

Life cycle stage 3: average age of children is between six and 12 years.

Life cycle stage 4: average age of children is between 12 and 17 years.

Life cycle stage 5: average age of children is over 17 years.

Life cycle stage 6: no children are present and the housewife is over 40 years age.

Because household size and composition account for a significant proportion of variation in food expenditure patterns across similar families, the income and expenditure data were adjusted separately, using an adult-equivalent scale, before estimating the Engel function.[4] The adult-equivalent scale is simply a device for specifying the requirements or expenditures of an individual of a particular age and sex as a proportion of the standard or base individual such as an adult male. The adjustment of the food expenditure and income variables makes the estimation of one Engel function for households of varying sizes, ages, and compositions possible. The procedure prevents attributing to income or food expenditures part of the variation properly attributable to variations in the age, sex of household members, or the effects of family size. Engel curves were estimated for sample households stratified according to their stage in the life cycle.

Methodology

Economic theory provides no a priori rationale for the appropriate functional form for the Engel relationship, although it does indicate that the functional form selected should obey the "adding-up" criterion (Salathe, p. 11). Yet the choice of functional form can influence substantially the estimated income elasticity. The linear and double-logarithmic tend to be the most commonly used functional forms, but empirical studies indicate the income elasticity of food is below unity and falls as income rises. This implies that both the linear functional form with rising elasticity and the double-logarithmic form with constant elasticity are inappropriate for the analysis of Engel relationships (Zarembka).

In this study Engel relationships were estimated using a Box-Cox transformation, for which the linear and logarithmic forms are special cases (Box-Cox, Chang, Zarembka).[5] To begin this anal-

[2] In that study a sample of SNE members were surveyed concerning the correct definition of a "nutritious" food so that recommendations could be made regarding a proposed Federal Trade Commission Trade Regulation Rule on the use of the term "nutritious" in food advertising.

[3] Pennington in her "Dietary Nutrient Guide" defined the first seven nutrients as key nutrients whose presence in sufficient amounts are indicators of the adequacy of a larger group of essential nutrients. She states that if one obtains the suggested daily intake of the index nutrients from natural foods and follows a few other suggestions, then the diet will be adequate in approximately all essential nutrients. Inclusion of adequate amounts of vitamin A and folacin will contribute to the vitamin E requirement but will not ensure it. The authors, thus, felt justified in including vitamin E as an index nutrient.

[4] Index values for food equivalent scales are from, Price *et al.*, vol. 2, chap. 9, p. 51. Estimates were developed by Price from the USDA 1965 Household Food Consumption Survey. For the analysis, further adjustments were made to reflect economies of size resulting from additional children as discussed in Price, p. 229, table 1. See Price for additional explanation and discussion. For explanation of derivation of income index values see USDL.

[5] When $\lambda = 1$, equation (1) is linear and when $\lambda = 0$, equation (1) is double logarithmic. In the linear case, $\lambda = 1$, and the income elasticity,

ysis the general functional form of the Engel Curve is written:

$$(1) \qquad C_i^{(\lambda)} = a_0 + a_1 Y_i^{(\lambda)} + U_i,$$

where C_i is the amount of food expenditure per food-adult equivalent, Y_i is income per income-adult equivalent, and U_i is the disturbance term of the cross-sectional group or household. The variables $C_i^{(\lambda)}$ and $Y_i^{(\lambda)}$ are defined as:

$$(2) \qquad C_i^{(\lambda)} = (C_i^{\lambda} - 1)/\lambda, \text{ and} \quad Y_i^{(\lambda)} = (Y_i^{\lambda} - 1)/\lambda,$$

where λ represents a transformation parameter to be determined. The U_i term for the given λ's is assumed to be normally and independently distributed with zero mean, constant variance, and zero covariance. The income elasticity of food demand, N_y, can be shown to be

$$(3) \qquad N_y = a_i(Y_i/C_i)^{\lambda}.$$

The sign of the income elasticity depends on the sign of a_i, since Y_i and C_i are nonnegative values but its value depends on the relationship of Y_i to C_i and the value of λ.

Given the above assumptions for U_i and using the Box-Cox maximum likelihood approach, the logarithm of the likelihood function for a given λ that is to be maximized is, disregarding the constant,

$$(4) \; L_{\max}(\lambda) = -\frac{N}{2} \ln \hat{\sigma}^2(\lambda) + (\lambda - 1) \sum_i \ln C_i,$$

where $\hat{\sigma}^2$ is the estimated error variance of the regression of $C_i^{(\lambda)}$ on $Y_i^{(\lambda)}$. Maximization of (4) over the entire parameter space requires selection of alternative values of λ over a reasonable range, the regression of $C_i^{(\lambda)}$ on $Y_i^{(\lambda)}$ and the determination of the transformation parameter $\hat{\lambda}$ that maximizes (4). An approximate $(1 - \alpha)$ confidence interval for λ can be defined since $2[L_{\max}(\hat{\lambda}) - L_{\max}(\lambda)]$ is approximately distributed as χ^2 with one degree of freedom. That is, the $(1 - \alpha)$ confidence interval for λ is obtained by finding that value on either size of $\hat{\lambda}$ such that $L_{\max}(\hat{\lambda}) - L^{\max}(\lambda) = \frac{1}{2}\chi_1^2(\alpha)$.

C_i was further subdivided into foods that are relatively more nutritious and foods that are relatively less nutritious components of diets, so three general equations were estimated. Households also were separated into life cycle groups. Average income and expenditure on all food and relatively more or less nutritious components of diets appear in table 2. Average household income, it appears, is higher

Table 2. Average Annual Household Income and Expenditure on All Food and Relatively More or Less Nutritious Foods at Each Stage of the Life Cycle

Lifecycle Stage	Income	All Food	Relatively More Nutritious food	Relatively Less Nutritious Food
	($)			
0	5,603.96	1,207.92	1,037.68	170.24
1	12,610.41	2,025.05	1,740.28	284.77
2	11,369.67	2,885.97	2,478.17	407.80
3	12,901.33	3,743.19	3,178.67	564.52
4	14,002.51	4,099.24	3,511.75	587.49
5	14,716.19	3,461.66	2,958.41	503.25
6	10,551.08	2,570.11	2,203.64	366.47
All	11,316.97	2,772.01	2,372.26	399.75

for each succeeding stage in the life cycle, excepting stage two, until stage five is reached. It then declines. Average expenditure on all food and relatively more and less nutritious food increases until stage four is reached and then declines. Food expenditure, apparently, increases with the addition of children to the household and continues to increase as the children grow older, peaking when they are teenagers.

Results

Both expenditure and income per adult equivalent were transformed as indicated in equation (2) by λ's valued at intervals of 0.01 between -1.00 and 1.00. $C_i^{(\lambda)}$ was then regressed on $Y_i^{(\lambda)}$ for each set of the transformed data. $L_{\max}(\lambda)$ was calculated for each regression by using equation (4). Estimated coefficients and related statistics for the various regressions are given in table 3. R^2 values are all very low. This is not unusual in cross-sectional studies. The maximum likelihood estimates for λ, $\hat{\lambda}$ ranged from .16 to .47, which is distinctly different from zero or one. The 95% confidence interval for each $\hat{\lambda}$ varied approximately .02 to .08 from the maximum likelihood estimates for λ, $\hat{\lambda}$. Neither $\lambda = 1$ nor $\lambda = 0$ fell within the 95% confidence interval. The null hypothesis that the functional form was linear (H_0:$\lambda = 1$) or logarithmic (H_0:$\lambda = 0$) could be rejected at the 5% level of significance. Coefficients of $Y_i^{(\lambda)}$ in all equations excepting life cycle stages 0 and 1 were significant at the 5% level.

The general functional form was considered to be a more accurate representation of the Engel curve. Income elasticities for the general functional form were represented by $N_y = a_i\left(\frac{Y_i}{C_i}\right)^{\lambda}$ and were also considered to be better estimates of income elasticities. Table 3 contains the estimates of the income elasticity at the means for all six life cycle stages for all food, and relatively more and less

$$N_y = a_i \frac{Y_i}{C_i} = \left(\frac{a_0}{a_i Y_i} - \frac{1}{Y_i} + \frac{U_i}{a_i Y_i} + \frac{1}{a_i Y_i} + 1 \right) - 1,$$

tends toward one as Y_i increases; in the log case, $\lambda = 0$, and $N_y = a_1$, the standard constant elasticity result. The semilog, hyperbolic, and log-reciprocal forms also can be shown to be special cases of the general form.

[c] Income elasticities measured at the mean value of income and consumption for each of the life cycle stages.
[d] Chow tests for a_i for regressions for relatively more and relatively less nutritious foods using linear and logarithmic forms indicated there were significant differences between the a_i's in every stage of the life cycle. For the justification of the Chow test for this type of problem see Toyoda. The Chow test is well behaved even under heteroscedasticity as long as at least one of two sample sizes is very large.
[e] At the maximized λ.

nutritious foods derived at the maximum value, $\hat{\lambda}$, for the general functional form. For all food, the highest income elasticity derived was for Stage 4 ($\hat{\lambda}$ = .45) and the lowest for Stage 0 ($\hat{\lambda}$ = .34). For foods that are relatively more nutritious components of diets, the income elasticity was highest for Stage 6 (no children present and the housewife was over 40 years of age ($\hat{\lambda}$ = .27) and lowest for Stage 1 ($\hat{\lambda}$ = .31). For foods that are relatively less nutritious components of diets, the income elasticity was highest for life cycle Stage 5 ($\hat{\lambda}$ = .22), when the average age of the children is over 17 years, and lowest for Stage 0 ($\hat{\lambda}$ = .16). As households move from "single persons" to "married with small children" (under six years) their food expenditure response to an increase in income increases for all foods, relatively more nutritious and less nutritious foods. This increased food expenditure response continues for relatively less nutritious foods throughout child-rearing ages and decreases for older person households when children are gone. However, for all foods and foods that are relatively more nutritious dietary components, the food expenditure response is more volatile. When children are between six and twelve years, there is a noticeable decline in the income elasticity. This response then rises and reaches a peak when children are in the teenage years, declines again when children are over seventeen and increases for older person households. Thus, the elasticities imply (*a*) households will spend a greater proportion of a greater income on all food when there are teenagers in the household; (*b*) older households without children will spend a greater proportion of a greater income on relatively more nutritious foods, and (*c*) households where the children are older and some, in fact, are young adults, will, on the average, spend the greatest proportion of a greater income for relatively less nutritious food. The further implications are that as the average age of the children in households increases, households will spend a greater proportion of a greater income on foods that are relatively less nutritious components of diets; and that as the proportion of older households without children increases, a greater proportion of greater household incomes will be spent on relatively more nutritious foods.

Summary and Conclusions

Income elasticities for all food, relatively more nutritious and less nutritious components of diets for all stages and seven designated life cycle stages, were estimated using the general functional form utilizing a Box-Cox transformation as proposed by confidence interval for λ varied no more than .08 from the value of $\hat{\lambda}$. The hypothesis that the linear or logarithmic functional forms which were also estimated fit the data was rejected at the 5% level.

Using the mean value in the estimating equations, the highest income elasticity using the flexible functional form was for Stage 4 (average age of children between 12 and 17 years) and the lowest for Stage 0 (single people) for all food. This is logical since food is a higher priority for households, generally, if they have teenage children and a lower priority for single people.

Interestingly, the income elasticity for the relatively more nutritious food components was highest for Stage 6. This implies that older people have a greater appreciation for nutrition. Nutrition education efforts to be most cost-effective should be directed to other household groups. For less nutritious food, the highest income elasticity was for Stage 5 (where the average age of the children was over 17 years). It may well be that relatively less nutritious foods are more appealing to teenagers and young adults. This has serious implications. Greater nutrition education efforts should be directed at those two groups who are just entering the labor force and for whom, over the lifetime, better health and higher productivity will have higher economic and noneconomic payoffs than for older persons.

Thus it would appear estimates of income elasticities based on linear and logarithmic functional forms may require reevaluation. Specific policy-relevant findings from this study indicate single-person households have lower income elasticities than households in any other life cycle stage for all food and for relatively less nutritious foods, while older people in childless households have the highest income elasticity for relatively more nutritious foods. This may not accord with the preferences of those who would prefer households with younger children and younger, more productive, adults to spend high proportions of higher income on more nutritious foods.

The Impact of Changing Marketing Margins on Farm Prices

B. S. Fisher

An important issue in the debate about the cost of marketing services is the incidence of a change in the charges associated with marketing an agricultural product. Traditionally the treatment of this question has been divided into two parts, the first being consideration of the incidence of charges associated with the introduction of new services and the second, consideration of the incidence of a change in the cost of an existing service. This note will deal with the latter.

The incidence of a change in the cost of existing marketing services may be explored graphically by the methods outlined by Tomek and Robinson (pp. 120–4). Although it is possible to arrive at broad conclusions about the incidence of changes in the level of marketing costs, it is difficult to quantify these effects using graphical methods. However, by employing a diagram such as figure 1 (c), it is possible to derive a relationship which may be used to quantify the effects of an exogenous change in marketing charges on retail and farm prices. For ease of illustration it is assumed that the market operates on only two levels, that is, the farm level and the retail level.

In figure 1 demand at the retail level is denoted as Dx. Supply at the farm level is denoted as S. For present purposes it is assumed that the quantity of the good is measured in terms of retail weight. The demand for the marketing services needed to transform the good as it moves through the marketing chain can be derived as the vertical difference between supply at the farm level and demand at the retail level. The derived demand for marketing services is denoted as Dm. In the present paper it is assumed that the supply of marketing services, Sm, is perfectly elastic. Such a case would exist, for example, where there is excess capacity in the service industry. The interaction of the demand and supply of service functions establishes the price paid for services, that is, the marketing margin. The margin before the change in the cost of existing marketing services is the difference between Px_0 and Pa_0, that is, the difference between the retail price and the farm price.

With reference to figure 1 (c), it can be seen that a small change in the margin, δM, represented by the difference between Sm_1 and Sm_2, leads to a change in both the retail and the farm price and a change in the quantity sold, δQ. The present paper is concerned only with cases where the change in the marketing margin is a result of exogenous shifts in the supply of marketing services, such as that caused by an increase in real wages, for example. The change in the margin, δM, can be decomposed into its effect on the farm and retail prices. That is,

$$\delta M = r + f, \tag{1}$$

and the proportion of the increase borne by the farmer is given by

$$I_f = f/(r + f). \tag{2}$$

If it is assumed that the demand and supply curves are linear over the range, δQ, then the distances r and f are related to the slopes of the demand and supply curves, respectively. Although empirical estimates of the slopes of demand and supply response functions are often reported in the literature, these are of little use in a general analysis because slope estimates are dependent on the units of measurement chosen by the investigator. For general application it is necessary to have a formula based on elasticity estimates because these are readily available, widely understood, and independent of the units of measurement. Such a formula can be derived using figure 1 (c). From the diagram it can be seen that the direct price elasticity of demand at equilibrium is

$$\eta = \frac{\delta Q}{r}\,\frac{Px}{Q}, \tag{3}$$

and that the direct price elasticity of supply is given by

$$e_a = \frac{\delta Q}{f}\,\frac{Pa}{Q}. \tag{4}$$

Reexpressing equations (3) and (4) with r and f on the left-hand-side and substituting into equation (2) results in an expression for the farmers' share of an increase in marketing charges. This relationship can be written as

$$I_f = \frac{1}{1 + e_a/\alpha\eta}, \tag{5}$$

where $\alpha = Pa_0/Px_0$ and η takes its absolute value.

It is immediately obvious that farmers will pay 100% of any increase in marketing charges if the elasticity of supply is zero. In the case where

---

B. S. Fisher is a lecturer in the Department of Agricultural Economics, University of Sydney.

The author benefited from comments on an earlier draft of this paper by Keith Campbell, Carolyn Tanner, Carolyn Rattigan, and two anonymous referees.

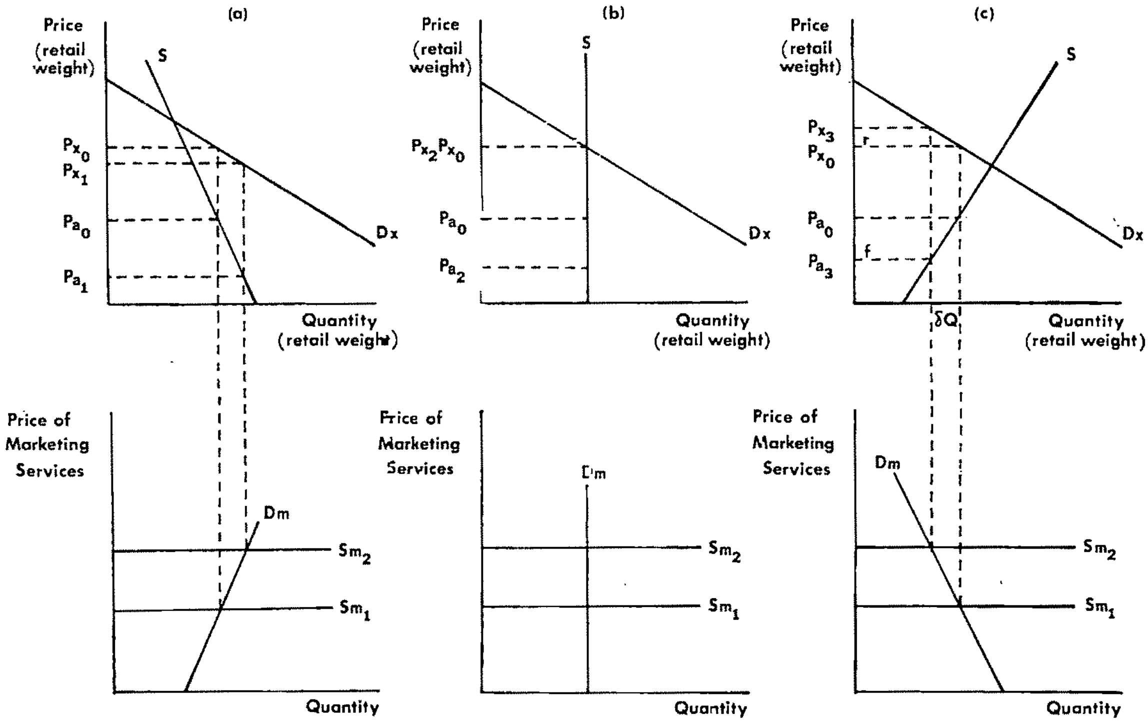

Figure 1. Producer and consumer shares of an increase in marketing charges given different elasticities of supply

$e_a = \alpha\eta$, the increase in charges is shared equally between producers and consumers.

The graphical approach and the resulting equation for the farmers' share of an increase in charges for existing marketing services depends implicitly on the assumption that the elasticity of substitution between agricultural products and other inputs into the marketing sector, σ is zero. This assumption can be relaxed if a mathematical model of a competitive marketing sector, such as the one outlined by Gardner (pp. 399–409), is used. The model employed by Gardner consists of six equations describing a food-processing sector which uses two factors of production, agricultural products and other marketing inputs. The market is described by a production function, a retail demand equation, two input supply equations and two equations setting out the marginal conditions for profit maximization. The effect on market equilibrium of a change in the cost of existing marketing services can be analyzed by differentiating the equations in the model with respect to the cost of marketing services. Using Gardner's nomenclature, this results in a three-equation system of the form:[1]

$$(6)\quad O = -\left[\frac{S_b}{\sigma} + \frac{1}{e_a}\right]E_{aT} + \frac{S_b}{\sigma}E_{bT} + E_{p_xT}$$

[1] See Gardner (p. 400 and appendix) for details of the derivation of this system.

$$(7)\quad e_T = \frac{S_a}{\sigma}E_{aT} - \left[\frac{S_a}{\sigma} + \frac{1}{e_b}\right]E_{bT} + E_{p_xT},$$

$$(8)\quad O = S_aE_{aT} + S_bE_{bT} - \eta E_{p_xT},$$

where a and b are the quantities of the agricultural product and the other marketing inputs, respectively; S_a and S_b are the relative shares of a and b, for example, $S_a = aP_a/xP_x$; e_b is the own price elasticity of supply of marketing inputs other than agricultural products; and E_{aT} E_{bT}, and E_{p_xT} are total elasticities which indicate how the first subscripted variable responds to a change in T. T. represents an exogenous factor which shifts the supply of marketing services upward, thus increasing the price of the services.

The farmers' share of an increase in marketing charges is given by the expression

$$(9)\quad I_f = \frac{|\delta p_a/\delta T|}{|\delta p_a/\delta T| + |\delta p_x/\delta T|}.$$

Solving the system of equations (6), (7), and (8) to obtain expressions for the partial derivatives in (9) and substituting into (9) results in the following expression for the farmers' share of an increase in marketing charges.

$$(10)\quad I_f = \frac{\left[\frac{\eta}{\sigma} + 1\right]\frac{\alpha}{e_a}}{\left[\frac{\eta}{\sigma} + 1\right]\frac{\alpha}{e_a} + \left[\frac{1}{\sigma} + \frac{1}{e_a}\right]},$$

where η takes its absolute value. Taking the limit of equation (10) as σ approaches zero gives equation (5), the result obtained from figure 1(c).

Equations (5) or (10) may be used to show how the burden of any exogenous change in marketing charges will be shared by producers and consumers, given estimates of the necessary parameters. For example, the equations may be used to analyze the effect on the price received by farmers of an increase in wage rates in the service sector or an increase in the price of fuel. Both the aforementioned charges will cause the supply curve for marketing services to shift upwards, thus increasing the marketing margin. As an illustration, equation (5) has been used to show the incidence of a change in the cost of marketing services given different elasticities of supply and demand. Tables 1 and 2 illustrate the shares under the assumptions that $\alpha = 0.52$ and $\alpha = 0.34$, respectively. The values for α were calculated for the Sydney beef market over two time periods. The average value for α in the market for the period 1971 to 1978, excluding the years 1975 and 1976 was 0.52. The years 1975 and 1976 were years in which the farm price of beef was depressed. The average value for α in those years was 0.34. In the case of both tables it is assumed that $\sigma = 0.0$. The estimated shares are sensitive to a change in the assumption that the elasticity of substitution is zero. For example, for the combination $\eta = 1.3$, $e_a = 0.3$, $\alpha = 0.52$, and $\sigma = 1.0$, the farmers' share of an increase in the cost of marketing services is 0.48 compared to 0.69 in table 1. It is likely, however, that the elasticity of substitution of marketing services for beef is close to zero.

The above formulas are applicable in cases where the demand and supply curves have the usual slopes. An interesting case arises when the slope of the supply function is negative, something that may occur in the short run in the beef industry (see, for example, the evidence presented by Tryfos or Freebairn). The effect on prices at retail and the farm gate of a change in marketing charges when the supply elasticity is negative is illustrated in figure 1 (a). In this case the demand curve for marketing services is positively sloped and it is possible, therefore, that in some cases the market will not reach equilibrium. In the example illustrated by figure 1, an increase in the size of the margin is consistent with a lower price at both the farm and retail levels. The difference between Px_0 and Px_1 on figure 1 (a) could be thought of as the amount by which the farmers' share of an increase in marketing charges exceeds 100%. The time paths of prices at both levels in the market may be traced with the aid of figure 1. The figure illustrates the changes that would occur as adjustment takes place over time. The figure shows that as a result of an increase in charges, prices at both the farm and the retail levels initially fall and then, as further adjustment takes place, prices rise.

The present note explores the effects on retail and farm prices of a shift in the supply curve for marketing services. Such a shift could be caused by changes in exogenous factors, such as wage rates or the price of energy, for example. The formulas that have been derived show that for most agricultural products, the major adjustment to a change in marketing charges will be made by farm prices. Farmers therefore have a strong economic interest in promoting efficiency in the service sector.

Crop Production Costs and Returns on Midwestern Organic Farms: 1977 and 1978

Georgia Shearer, Daniel H. Kohl, Diane Wanner, George Kuepper, Susan Sweeney, and William Lockeretz

Increasing costs of energy have had a serious impact on the cost and supply of fertilizers, particularly nitrogen fertilizers. The use of several pesticides has been banned or restricted, and restrictions are being considered for others. For these reasons, a reduction in the chemical and energy intensiveness of agriculture would be desirable, provided that agricultural production would not be reduced seriously or production costs appreciably increased. Organic farming represents a lower bound on chemical intensiveness and consequently is considerably less energy intensive as well. A study of such farms can provide information on the effect of reducing the use of farm chemicals on productivity and economic performance.

We have previously reported results of a three-year comparison of economic performance and energy intensiveness of crop production on fourteen pairs of midwestern mixed grain-livestock farms which do (conventional farms) and which do not (organic farms) use standard commercial fertilizers and pesticides (Klepper et al., Lockeretz et al. 1978). The value of crops produced on organic farms, per unit area of cropland, was about 11% lower than on conventional farms. Operating expenses were also lower on organic farms and net returns about the same. Energy use for each dollar's worth of crops produced on organic farms was only 40% of that used on the conventional farms. Two major limitations in the three-year comparison restrict the applicability of the results. First, the sample was small and selected in an ad hoc way, essentially by word of mouth, because no listing of organic farms was available when the study began. Second, the data were obtained during three years of relatively unfavorable conditions. On the basis of both agronomic principles and empirical measurements (Lockeretz et al. 1980), relative yields on organic farms compared to conventional farms can be expected to be better under adverse than under favorable growing conditions.

Because of these limitations, we extended our analysis of crop production on organic farms by analyzing a different sample for two additional years, 1977 and 1978. The results are reported in this paper.

Methods

In this section, we describe briefly this new sample, both the organic farms and the comparison farms. Then we discuss the cost and revenue calculations that form the basis of our analysis.

Selection of Farms

The organic farm sample for this study was drawn from a survey (Wernick and Lockeretz) which identified more than 250 farmers in the western Corn Belt who do not use standard commercial fertilizers or pesticides, who produce field crops (generally in association with livestock), and whose farms are over 40 hectares in size. For this study, we limited our sample to the crop enterprises of beef and hog-producing farms in Iowa, southern Minnesota, and northern Illinois that had been soil mapped. The twenty-three organic farms in the 1977 analysis represent all of the organic farms in our survey which met the above criteria and whose operators were willing to cooperate in the study. In 1978, the number of cooperating organic farms dropped to nineteen. Most of the sample farms were in Iowa (eighteen in 1977 and fifteen in 1978).

Whenever possible, the sample organic farms were compared to all beef and hog farms in each of the counties in which the organic farms were located. Depending on available data, some comparisons (notably, crop yields) were made with all farms, not just beef and hog-producing farms, in each of the counties.

The average farm size of the 1977 organic sample was 95.1 hectares, compared to 95.6 hectares for all beef and hog farms in the relevant counties (U.S.

Department of Commerce). Here farm size refers to the amount of cropland, set-aside land, and permanent pasture. Farm buildings and woodland are not included. Although the average size of the two kinds of farms was nearly equal, the distribution of farm sizes was not. Organic farms under 40 hectares were excluded from the sample, whereas the group of beef and hog farms in the relevant counties included all sizes.

Land Capability

The quality of the land on the organic sample was compared to that on all farms in the relevant counties by determining the proportion of farmland in each capability class. For organic farms soil maps were used for this determination. For all farms in the same counties, the fraction of farmland in each capability class was taken from statistical sources (Illinois, Iowa, and Minnesota Conservation Needs Committees, and Soil Conservation Service).[1] The proportion of farmland in capability classes I and II (prime cropland) was 54% for the organic farms and 68% for all farms in the same counties. Capability classes I–IV (land suitable for cropping) accounted for 94% of the organic farmland and 96% of all the farmland in the same counties. Thus, the quality of the land on the organic sample and on all farms in the same counties was very similar. In both years, the percentage of land in classes I and II on organic farms was significantly and positively correlated with the comparable percentage for all farms in the relevant counties (1977: $r = 0.70$; 1978: $r = 0.62$, slope = 1.05). This shows that individual organic farms were roughly similar to all farms in the same counties in the fraction of land that is prime cropland. Most of the land suitable for cropping (94% of classes I–IV) was used for that purpose on organic farms.

Crop Mix

The crop mix on the organic sample was obtained from information supplied by the farmers. The only data on crop mix available for other farms were statewide data by type of farm for 1974 (U.S. Dep. of Commerce) and county-wide data for all types of farms for 1977 and 1978 (Illinois Cooperative Crop Reporting Service, Iowa Crop and Livestock Reporting Service, Minnesota Crop and Livestock Reporting Service). We estimated, for 1977 and 1978, the crop mix for all beef and hog farms in the relevant counties using the following assumptions: for a given crop and a given county, the fraction of land in that crop on a particular type of farm in 1977 or 1978 stood in a fixed ratio, independent of farm type, to the fraction of land in that crop in 1974 on all farms of that type in the state; the relative average farm size for the various types in a given county was the same as for the state as a whole; the proportional number of farms of each type in a county remained constant from 1974 to 1978.[2] Because of lack of data, we further assumed that oats are a constant fraction of the land in hay in each county, oats being raised primarily as a nurse crop for hay. The Census data on rotation and permanent pasture are unreliable, because farmers apparently do not distinguish consistently between the two, although the total pasture is correct. We therefore used the 1977 National Erosion Survey (Soil Conservation Service) to determine the proportion of land in permanent pasture in each state, and deducted the amount of rotation pasture from the Census data on total pasture. We further assumed that the ratio of rotation to permanent pasture for beef and hog farms in a given county was the same as for all farms in the state. From these assumptions, and the data sources, indicated, we estimated crop mix on all beef and hog producing farms in each county in 1977 and 1978.

Yields and Market Value of Production

Crop yields on organic farms were taken from farmer reports. A previous comparison of measured corn grain yields with yields as reported by farmers showed close agreement (Lockeretz et al. 1980). These yields were compared to yields on all farms in each respective county as reported in Agricultural Statistics (Illinois Cooperative Crop Reporting Service, Iowa Crop and Livestock Reporting Service, and Minnesota Crop and Livestock Reporting Service). Hay yields on organic farms in Minnesota and Illinois were the same as on all farms in the corresponding counties. On this basis, hay yields on organic farms and on all farms in the relevant counties in Iowa, which does not report hay yields, were assumed to be equal.

In all cases, the market value of production was calculated using season average prices reported by USDA Statistical Reporting Service. Organic farms were not credited with any premium price for their products. A previous survey (Wernick and Lockeretz) showed that premium prices are not a significant factor on this type of organic farm.

Expenses

Only operating costs were considered. Fixed costs were assumed to be the same on both kinds of

[1] For all farms in the relevant counties, the fraction of farmland in each capability class was taken from the 1967 Conservation Needs Inventory (Illinois, Iowa, and Minnesota Conservation Needs Committees). The 1977 National Erosion Survey (subject to revision) (Soil Conservation Service) showed little change in the area of farmland or the distribution of this land within capability classes between 1967 and 1977.

[2] For example, suppose that in the state as a whole in 1974, 50% and 25% of the land on cash grain and beef and hog farms, respectively, was in corn. Suppose also that the proportion of cropland in corn in a particular county in 1977 was 1.2 times that of the state in 1974. Then according to our assumption, 60% (1.2 × 50%) and 30% (1.2 × 25%) of the land on cash grain farms and beef/hog farms, respectively, in that particular county would be assigned to corn.

farms. This assumption seems justified in light of our previous finding (Lockeretz et al. 1975) that organic and conventional farms are virtually identical in machinery, equipment, and land quality. Methods of estimating operating costs on organic farms have been described previously (Lockeretz et al. 1975). The number of individual operations involved in crop production and the rate of application of materials, such as fertilizers, pesticides, and soil amendments, on county farms were taken from the Firm Enterprise Data System (USDA ERS) except that these farms were credited with the full fertilizer value of all manure produced.[3] Costs of inputs (with the exception of organic fertilizers, the cost of which was taken from farmer reports) were based on data given by USDA Statistical Reporting Service.

Energy Use for Crop Production

The methods we used to estimate energy use for crop production have been described previously (Lockeretz et al. 1975, Lockeretz et al. 1976). Estimates were based on fuel consumption for field operations and energy consumption for the production of materials used. Energy consumption for production of machinery and equipment and for transport of crops to market was not included.

Results

This section presents the major results of our analysis. Where possible, we present direct comparisons between the organic farms and the others.

Crop Yields

Table 1 shows average yields in metric tons per hectare (MT./ha.) of the predominant grains grown on the organic and county farms in 1977 and 1978. In 1977 the average organic corn yield was 8% lower than the average county-wide corn yield, soybean yields were nearly the same for the two groups, and oat yields were about 10% higher on organic farms. The low average corn yields on both kinds of farms in 1977 reflect serious drought in several of the counties.

1978 presents a different picture. It was an unusually favorable growing year throughout the western Corn Belt. Organic corn yields were about 18% lower than those on all farms in the relevant counties, a difference that was significant at the 99% confidence level. Organic soybean yields were about 7% lower, and oat yields were 6% higher on organic farms. The differences in soybean and oat yields were not significant.

Table 1 also shows that organic and county yields for a given crop were significantly correlated with each other. This indicates that the organic farms were similar to all farms in the corresponding counties with regard to enviornmental factors that affect yields.

Fraction of Total Farmland in Various Uses

Table 2 shows land in crops, permanent pasture, and the set-aside program. (Land use for other purposes, such as buildings and woods, is not included.) Less land is used for corn on organic farms than on all-beef and hog-producing farms in the corresponding counties. More land is used for oats, a nurse crop for hay, on organic farms. The total fraction of land in hay and pasture is about the same on the two kinds of farms. However, less of this land is in permanent pasture and more in rotation hay and pasture on the organic farms. Although there may be differences in erosion resulting from the difference in crop mix, we do not assign a dollar value to this.

Costs and Returns for Crop Production

Table 3 gives economic data for each of the major crops and for all crops. The first column of table 3

[3] The fertilizer value of manure was computed from the density and type of livestock, taking into account its nutrient content (Ensminger), handling losses, and the effectiveness of manure nutrients compared to commercial fertilizers (Ensminger, Peele et al., and Tisdale and Nelson). Livestock density and type were estimated by methods analogous to those used for crop mix.

shows the value of production per hectare of cropland. In the poor growing year, 1977, the only crop that showed a significant difference in value of production between the two kinds of farms was oats. However, oats are grown mainly as a nurse crop for hay. Soybeans yielded the highest value of production on both kinds of farms. The value of hay and rotation pasture was somewhat higher than that of corn in 1977. The high value of hay and rotation pasture compared to corn arises from the high current price of hay compared to corn, and low corn yields in 1977. Expenses were highest for corn, with the result that in 1977, the highest net returns were from soybeans, followed by hay and rotation pasture, with corn coming in a poor third. In 1977 there were no significant differences between organic and conventional net returns for any of the crops except oats, for which net returns on organic farms were higher.

Under the more favorable growing conditions of 1978, corn—the crop which is apparently most vulnerable to adverse conditions—became more profitable. In 1978, the most profitable crop again was soybeans, with corn about equally as profitable as hay and rotation pasture. The value of production of corn was significantly higher on all farms in each county than on organic farms. However, because of differences in expenditures, there were no

Table 3. Average Costs and Returns from Crop Production on Organic Farms and All-Beef and Hog-Producing Farms in the Same Counties ($/ha. of cropland)

Year / Crop	No. of Organic Farms	Value of Production		Operating Expenses		Net Returns

All Crops	19	440	527[c]	107	143[c]	333	384[a]

[a,b,c] Differences between organic and all farms statistically significant at the 90%, 95%, and 99% levels, respectively (based on 2-sided t-tests for paired samples).

significant differences between the two kinds of farms in net returns for any of the individual crops in 1978.

Expenses on organic farms were lower for corn and soybeans and higher for oats and hay than on all farms in each county. The lower expenses for corn production on organic farms reflect the nonuse of standard fertilizers and pesticides. The higher expenses for the production of oats, hay, and rotation pasture on organic farms reflect a practice common among organic farmers—the application of commercial organic soil amendments of negligible nitrogen, phosphorus, and potassium (N, P, K) content to hay and oats. In contrast, conventional farms add few, if any, amendments to hay or oats.

Table 3 also shows whole-farm costs and return for crop production, calculated by combining the data on individual crops and on the proportional area in each crop (from table 2). In 1977, the year in which growing conditions were poor, the average value of crops produced on organic farms was only slightly lower than on all farms of the same type. Expenses were also lower, and net returns for the two groups were similar. In contrast, in 1978, a year in which growing conditions were well above average, the value of production on organic farms was considerably lower than on all-beef and hog farms in the same counties. The difference between the two groups in expenses was almost the same in the two years. But in 1978, unlike 1977, the difference in value of production was too large to be offset by the difference in expenses; net returns were lower (13%) on organic farms.

Energy Consumption

Energy use per dollar of crops produced is shown in table 4. The most energy-intensive crop on both kinds of farms was corn, which also shows the largest difference between the two groups in energy use. The overall lower energy use on organic farms is because of their lower energy use for corn together with the smaller proportion of cropland in corn. Energy use per dollar of crops produced on all-beef and hog farms was lower in 1978 than in 1977 because of higher production in 1978, rather than lower energy inputs per unit area.

Conclusions

The results support our earlier conclusion (Klepper et al., Lockeretz et al. 1978) that under unfavorable growing conditions, crop production on organic farms is as profitable as on conventional farms. In contrast, under favorable growing conditions, conventional farms outperform organic farms.

Despite major differences in agricultural practice between the two kinds of farms, differences in net returns were modest, even under conditions which were extremely favorable for conventional practice. This gap may narrow if costs of chemical inputs rise, although simultaneous changes in other costs and in crop prices may obscure this effect.

The results of this study show that an alternative agricultural system characterized by a different crop mix and markedly less chemical input, produced crop yields and net farm income which were close to those achieved on conventionally managed, commercial-sized, midwestern Corn Belt, mixed crop/livestock enterprises. We believe that an examination of productivity under management intermediate between the extremes studied here would be fruitful. It is important to explore the possibility of successful agriculture with fewer

Impacts On Farmers of a Computerized Management Decision-Making Model

David L. Debertin, Charles L. Moore, Sr., Larry D. Jones, and Angelos Pagoulatos

A number of states are currently developing comprehensive programs for making computerized decision aids available to farmers (Harsh; Infanger, Robbins, Debertin; LaDue; Schoonaert; Walker). While Cernea and Tepping have outlined procedures for a general evaluation of agricultural extension projects, only a few efforts have been conducted with a corresponding research effort aimed at quantifying the impacts of computerized decision models on farmer behavior. (Erickson; Erickson, Sandborg, Byers; Knoblauch). This paper summarizes results from a pilot research project designed to provide measurements of changes in farmer behavior as the result of being exposed to a computerized planning model in extension.

This study is an attempt to determine the specific management decisions that the farmers intended to make as a result of having been exposed to the planning model. A follow-up effort one year later identified managerial decisions that actually had been implemented as a result of exposure to the planning model a year earlier. Hence, both farmers' intentions and realizations were measured in this study.

The Experimental Design

Twenty-six commercial corn and soybean farmers were invited to participate in a workshop at the University of Kentucky using the KASH PROFITS computerized planning model. The KASH PROFITS model is a linear programming model designed to assist corn and soybean farmers in making planting, tillage, harvesting and other management decisions. It is a modified version of model B-90 originally developed over several years at Purdue, and is perhaps the most widely used comprehensive computerized management model in extension education. Details of the model construction can be found in a number of research and extension publications (Brink, McCarl, Doster; Debertin et al.). Because of its widespread use, the model has been subject to a more thorough testing under actual farmers' conditions than have most other computerized decision aids, and the behavior of the model is normally quite reliable (McCarl et al.).

The farmers participating in the three-day workshop were not a random sample, but were representative of progressive commercial grain farmers in Kentucky. Nearly all were members of Kentucky's farm business analysis program, a record and analysis system sponsored by the Department of Agricultural Economics. Acreages, ages, educational levels did vary widely (table 1).

At the conclusion of the workshop, each farmer was asked to complete a questionnaire which requested detailed information with regard to the specific changes the farmer intended to make as a result of having used the model over the three-day workshop session. One year later, a follow-up questionnaire was mailed to each farmer who had participated in the workshop. This questionnaire requested detailed information with regard to the specific changes that were implemented as a result of their workshop experience one year later.

One year may not be a sufficient length of time to measure the total benefits gained from an educational experience. For example, farmers may not have sufficient time to make major decisions involving factors such as those involved in the purchase of additional land or the acquisition of major items of machinery. However, a survey of farmers one year after a workshop with respect to the changes they implemented should provide a better estimate of the effectiveness of an educational experience than if survey data were gathered only at the workshop conclusion.

Experimental Results

For the initial questionnaire, the following survey responses were possible:

(1) I intend to make the change.
(2) I am undecided.
(3) I do not intend to make the change.
(4) If "no" or "undecided," it is because:
(a) I could not figure out my output.
(b) KASH PROFITS said a change was not profitable.
(c) KASH PROFITS does not represent my farm.
(d) I gave the computer the wrong information.

David L. Debertin is a professor; Charles L. Moore, Sr., is an associate extension professor; and Larry D. Jones and Angelos Pagoulatos are former extension professor and associate professor, respectively, Department of Agricultural Economics, University of Kentucky.

Table 1. Characteristics of Farmers Attending Workshop, 1976

	Mean	Range
Average age (years)	34.12	22–53
Years farming	11.62	1–31
Educational level (years)	15.17	11–19
Acres corn grown during 1976	534	39–1,754
Acres soybeans grown during 1976	280	0–870
Months of labor used on the farm (owned and hired)	43.6	6.6–159.1
Investment in machinery	$101,724	$13,699–$316,019
Farm and family earnings[a]	$128,007	$17,004–$381,031

Source: Debertin, Moore, and Jones.
[a] Defined as return to capital, operator's labor and management.

(e) Not enough time to make the change this year.

(f) I cannot make the change because of circumstances outside of my control.

On the follow-up questionnaire, the following survey responses were possible:

(1) No, I did not make the change.

(2) Yes, I did make the change as suggested by the model.

(3) I made a partial change.

(4) This question does not apply to my farming situation.

Table 2 summarizes the twenty-five questions contained on the initial and follow-up questionnaire.

Table 2. Survey Questions

As a result of the KASH PROFITS workshop, will (did) you:

a. change the acres of corn you grew?
b. change the acres of single crop soybeans you grew?
c. change the acres of wheat-double crop soybeans you grew?
d. change the acres of corn silage you grew?
e. change the acres of land you rented in?
f. change the acres of land you rented out?
g. change the amount of farm-held storage?
h. change the date you began planting corn?
i. change the date you began planting soybeans?
j. change the hours of labor you used during planting?
k. change the size and number of tractors for planting?
l. change the date when you began harvesting corn?
m. change the date when you began harvesting single crop soybeans?
n. change the hours of labor for planting?
o. change the hours of labor for harvest?
p. change the size or number of combines you used?
q. change the timing of land preparation?
r. change the timing of post-plant tillage?
s. hire in a custom combine for corn?
t. hire in a custom combine for soybeans?
u. hire in a custom combine for wheat?
v. hire in custom silage harvest?
w. hire out your combine?
x. purchase a farm dryer, or change the time of dryer used? used?
y. change the amount of crop you stored on the farm?

Table 3 summarizes results from the initial questionnaire that farmers completed at the conclusion of the workshop. At the end of the workshop, a substantial number of farmers indicated a desire to make some changes in their farming operations as a result of having used the model. Some thirteen farmers indicated they would adjust their corn acreages, and fourteen said they would change their soybean acreages as a result of having worked with the model (questions *a* and *b*). However, this was not true for some other decisions. None were willing to change the acres of land rented out (question *f*). Only one farmer indicated a willingness to change corn silage acreages (question *d*), the size or number of tractors (question *k*), or hire a custom combine for wheat (question *u*). Ten farmers indicated a willingness to change soybean planting dates (question *i*) while nine were willing to change planting dates for corn (question *h*). Nine farmers also indicated a willingness to change the hours of labor used during harvest (question *o*) and change the amount of farm stored crop (question *g*).

The most common reason for an unwillingness to make a change was that the model indicated the change was not profitable. For example, farmers at the workshop experimented with the option of adding a tractor or a new combine. In many instances, these experiments indicated that new machinery would not increase net returns.

Factors outside the control of the farmer was another common reason for not making a change. These factors include long-term lease-rental commitments, credit restrictions, and the unavailability of land to rent in or labor to hire. A few farmers indicated that they did not have time to make the change for the upcoming cropping season but would the following year. Output from the model is quite lengthy and complicated. However, there was little evidence that farmers participating in the workshop had difficulty interpreting their output, or that they supplied incorrect information to the model.

An analysis was conducted to determine the extent to which linkages existed in farmer responses to the questions on the evaluation forms. This was an effort to determine if a farmer who had been exposed to a computerized decision model tended

Table 3. Frequency of Response to Questionnaire at Conclusion of the Workshop

to make changes on certain kinds of decisions, but not to make changes on other decisions. For example, a farmer might be willing to change the timing of both planting and tillage and harvesting operations but be reluctant to make decisions dealing with capital investment such as for machinery or crop storage.

From the frequency counts contained in table 3, a correlation matrix was developed. The simple correlation coefficient between each pair of evaluation questions provided a measure of the extent to which each pair of questions was linked. Factor analysis is also useful in identifying major sources of variation in a data set, and was used here to supplement and verify the correlation analysis results. Four factors were found to summarize over 90% of the variation in the data set, and factor scores using a varimax rotation grouped the questionnaire responses into four distinct categories: (*a*) those dealing with corn and soybean acreages and crop storage decisions (factor 2), (*b*) those dealing with double-cropping and storage-building decisions (factor 3), (*c*) those dealing with corn silage planting decisions (factor 4), and (*d*) all other decisions (factor 1). Farmers tended to behave similarly within each category of decisions.

Table 4 summarizes results obtained from the initial questionnaire in relation to the follow-up questionnaire. Hence, the extent to which farmers' intentions become realizations is assessed.

Nearly all of the farmers who indicated that they would not make a change did not make a change. Of those that indicated they would make a change, most did not make the entire change suggested, but rather made a partial change. This was particularly true with respect to corn and soybean acreages. A relatively large number who indicated a willingness to make a change did not follow through. This was particularly true for decisions dealing with labor and timing of planting, tillage, and harvesting operations (questions *h, i, j, l, m, o, q, r, s, t, w,* and *x*). However, a number of farmers who indicated that they would not make a change with respect to these decisions on the initial survey subsequently made a partial change.

Correlation and factor analysis were again used to identify four categories of decisions: (*a*) those dealing with labor availability and timing of planting and harvest decisions (factor 1), (*b*) those dealing with corn and soybean acreage decisions (factor 2), (*c*) those dealing with corn silage (factor 3), and (*d*) all other decisions (factor 4). Each of these categories was linked in that farmers' decisions with respect to changes were similar within each category.

Table 4. Frequency of Response to Initial and Follow-up Questionnaire, One Year after Workshop

yes and does not apply	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	1	1	1	0	0	0	0	4	0.16

The follow-up questionnaire requested that each farmer estimate by how much the workshop experience increased farm profits. Table 5 summarizes the results. Findings were somewhat bimodal. Seven farmers indicated that they did not know how to estimate the increase in profits attributable to the workshop. Eight farmers felt that the workshop experience did not increase farm profits. Those who indicated a dollar figure placed their estimates at \$100 to \$16,000. Nine of the participants who provided estimates indicated that profits were increased the following year by less than the total direct costs of the workshop to them of \$252. However, four farmers estimated profits to be increased by \$10,000 or more.

Conclusions

Farmer decision making is impacted by exposure to a large-scale, computerized, planning model. However, the extent to which decisions are impacted by the model depends greatly on the nature of the specific decision being considered and the farmer's particular operation. Farmers were willing to make changes in decisions relating to crop acreages upon exposure to model information. They were much less willing to make changes relating to machinery purchases, labor utilization, and land rental. These decisions are often more difficult to implement than decisions dealing with changes in crop acreages. Moreover, farmers may not maximize profits, but rather satisfy a subjective desire for a new piece of machinery. The model usually found acreages to be suboptimally allocated. For other decisions the model often indicated that a change was not necessary. Hence, farmers were properly following the advice of the model by not making a change.

A second conclusion is that farmers' intentions often do not develop into realizations. In many instances, intended changes were not realized by the end of the production period. Even though farmers planned to make a specific change in their operation as a result of the workshop, these changes were often only partially implemented, or not implemented at all. In a few cases, farmers planned a no-change decision but then implemented a change during the cropping season.

The scope of the evaluation was somewhat narrow. In evaluating the results of the workshop, direct changes in certain decisions were observed, such as changes in acreages and the size of machinery. However, one of the major impacts on farmers may not be these direct changes that were observed, but rather the total impact of the model on making the farmer better aware of the strengths and problems associated with the business. This greater awareness of the business could lead to long-term adjustments not evaluated. Another benefit not evaluated is the fact that farmers were able

Table 5. Farmers Estimates of the Increase in Farm Profits for the KASH PROFITS Workshop, Follow-Up Questionnaire

Farmers Estimates of Value	No. of Farmers	Ratio of Increase in Farm Profits/Cost of Workshop
No way to determine or did not respond to question	7	—
Did not increase farm profits	8	0
Increased farm profits by (\$):		
100	1	.3967
500	2	1.984
2,000	1	7.936
3,000	1	11.905
5,000	1	19.841
6,000	1	23.810
10,000	3	39.683
16,000	1	63.492
Estimates of cost per farm:		
Registration fee (includes cost of:	\$100	
Computer time	(40)	
Keypunch operator salary	(20)	
Clerical assistant salary for checking input forms	(15)	
Banquet cost)	(25)	
Professional faculty time per farmer (6 hours @ \$12 per hour)	\$72	
Food and lodging costs	\$80	
Total costs per farmer	\$252	

to get away from their business for a few days to study the interaction of its parts. A number of farmers commented on this. This conclusion is in agreement with Stone and Erickson's arguments that providing a basic understanding of interactions within a business is one of the more important benefits of working with computerized decision models.

Finally, the perceived value of the workshop varied greatly among farmers. The evaluation one year after the workshop found farmers rather divided into two groups—those who felt the workshop was worth very little and those who felt the workshop was worth a great deal of money Further research is needed to verify findings in this analysis with respect to the extent to which computer models impact farmer decision making. A length of time between surveys greater than a year may be necessary to determine if farmers will make changes with respect to decisions such as land purchases.

The Inverse Relationship between Productivity and Farm Size: A Test Using Regional Data from India

Anil B. Deolalikar

The farm size-productivity debate for India needs little introduction; it has occupied a prominent position in the agricultural economics literature since 1962, when Sen observed that Indian farm management data revealed an inverse relationship between farm size and yields per acre. Since then, no fewer than twenty journal papers have appeared on this subject (Sen 1975).

The objective of this paper is to test two hypotheses that were either not given enough attention or left unresolved in the debate. The first is that the inverse relationship is valid for all of Indian agriculture; it is not merely a phenomenon observed in a few sample villages. This means a test of the hypothesis that the small farm sector as a whole is more productive than the large farm sector in Indian agriculture. The second hypothesis is that the inverse relationship is true only of a traditional agriculture, and that it breaks down with technical progress.

A methodology is developed below which uses cross-sectional regional data to test the two hypotheses simultaneously. On applying this methodology to Indian district-level data (272 districts) for 1970–71, it is found that the hypothesis of the small farm sector being more productive than the large farm sector cannot be rejected at low levels of agricultural technology, but can be rejected at higher levels. This suggests that the inverse relationship between yields and farm size, although valid for a traditional agriculture, cannot be assumed to exist in an agriculture experiencing technical change.

Previous Studies

A shortcoming of previous investigations into the inverse relationship was that they were based on microdata, collected in most cases by the Indian Farm Management Studies (FMS). Consequently, not much could be said about the relationship outside these sample districts. Indeed, data from non-FMS districts did not always bear out the inverse relationship. Using farm-level data from villages in Punjab, Haryana, and Uttar Pradesh, both Rudra and Rao (1967) could not detect any inverse relationship between farm size and yields. Saini, too, failed to find evidence of an inverse relationship in seven out of a total of twenty-five of his sample villages.

The inverse relationship thus has been far from an established fact: there always has been some controversy regarding its validity for all of Indian agriculture. None of the previous studies were able to answer satisfactorily the question: Is the small farm sector as a whole more productive (in the sense of having greater yields per acre) than the large farm sector? One reason for this inability was the use of a model which could use only microlevel data for the testing of the hypothesis. Typically, the model used by researchers was

$$Y_i = a + bX_i + e_i, \quad (1)$$

where Y_i is output or output per acre on farm i or group of farms i, X_i is size (in acres) of the farm or group of farms, and e_i is error term having zero mean, uniform variance, and no correlation with X_i. An estimated b coefficient less than unity (if Y is output) or negative (if Y is output per acre) then confirmed the inverse relationship.

Because X in equation (1) is expressed in absolute terms, the sample used in testing the hypothesis cannot extend beyond a fairly homogenous group of farms. For, obviously, a farm size of 10 acres does not mean the same thing in an arid region like Rajasthan as it does in an irrigated area like West Bengal. In the latter, it can be classified as a large farm size, but, in the former, it is clearly small. Farm size is thus a relative concept, and its measurement in absolute terms can be quite misleading, especially in a large and heterogenous sample.

Another issue that has not received much attention in the literature is that of technical progress in agriculture. A majority of the studies on the inverse relationship used data collected in the 1950s—almost a decade before the advent of the Green Revolution. This obviated the need for discussing the differential impact of technical progress on the productivities of small and large farms. The few studies that did use post-Green Revolution data arrived at ambiguous results. Bhattacharya and

The author wishes to thank Dennis Chinn, Todd Petzel, Pan Yotopoulos, and others present at a graduate research seminar at the Food Research Institute, Stanford University, where an earlier version of this paper was first presented. Assistance from an anonymous referee of this journal is also gratefully acknowledged. Responsibility for any remaining errors rests solely with the author.

Saini found, for instance, that the inverse relationship had changed after the Green Revolution in one district of the Punjab but had remained unchanged in another district. Using sample data for 1969–70 from West Godavari district, Rao (1975) found a positive relationship between output per acre and farm size. Bardhan confirmed the inverse relationship for Thanjavur district of Tamil Nadu but rejected it for Ferozepur district of Punjab. There is some theoretical basis for expecting the inverse relationship to be weakened, or even replaced by a positive relationship between yields and farm size, with technical change, but relatively few studies have systematically developed and tested this argument. This is discussed more fully in the next section.

Some Hypotheses

A priori there are several reasons for expecting small farms to have greater yields than large farms. For the sake of brevity, we discuss only the reason most commonly accepted by researchers in the field. First offered by Sen, the argument runs as follows: an imperfect labor market in a dual agricultural economy produces different shadow prices for labor to the small subsistence farmer, who uses his own labor on the farm, and the large commercial farmer, who relies mainly on hired labor. The imputed price of labor to the former is lower than that to the latter, resulting in a more intensive application of labor and complementary inputs on the small farm. This naturally raises the yields per acre on the small farm relative to those on the large farm.

Although the neat division between peasant and capitalist farming assumed by the above argument is somewhat exaggerated, there is some basis for the argument. Data have consistently shown that small farmers use more labor per acre than large farms (Bharadwaj). This must mean a lower valuation of own labor by the small farmer.

With technical progress, however, family labor becomes less important in determining land productivity,[1] while other current inputs like fertilizer become much more important.[2] Since the latter are factors whose use depends largely on cash and credit flows, large farmers—who have greater access to both—end up using more of these inputs than small farmers. The earlier adoption of the new technology by large farmers is a well-documented fact (Frankel, Griffin, Rao 1975)—one that reduces or even reverses the yield-advantage of small farmers.

[1] The share of labor in total output has been observed to decline with technical change, both by studies using cost-accounting data (Rao 1975) and by those fitting production functions (Chinn).

[2] Using a Taiwan sample, Chinn has estimated production elasticities of 0.185 and 0.226 for fertilizer for the periods 1960–62 (pre-Green Revolution) and 1970–72 (post-Green Revolution), respectively.

There is evidence to suggest that the Green Revolution has removed the yield superiority of small farms. Using 1958–60 data from West Godavari district, Rao (1975) found inverse relationships between output per acre, labor use per acre, and fertilizer use per acre on the one hand and farm size on the other hand. Using a 1969–70 sample from the same district, however, he obtained an inverse relationship only between labor use per acre and farm size. Output per acre and fertilizer use per acre were both positively related to farm size. This seems to suggest that large farms enjoy higher productivity than small farms in the post-Green Revolution period primarily because of their more intensive use of fertilizer and other modern inputs.

The Model

We start with the definition of average productivity in a district as the weighted sum of productivities of each size class of farms in the district, with the weights being the share of total land area cultivated by a size class. Since the land shares of all the size classes sum to unity, average district productivity can be written as

$$(2)\qquad Y \equiv s_1Y_1 + s_2Y_2 + \ldots + s_{n-1}Y_{n-1} + \left(1 - \sum_{j}^{n-1} s_j\right)Y_n,$$

where Y is average district productivity, s_j is share of total area operated by the jth size class of farms, and Y_j is productivity of the jth size class. Expanding the parenthetical term and rearranging all the terms, gives us

$$(3)\qquad Y \equiv s_1(Y_1 - Y_n) + s_2(Y_2 - Y_n) + \ldots + s_{n-1}(Y_{n-1} - Y_n) + Y_n.$$

Now, if district-level data on average productivity (Y) and on the distribution of land across various size classes of farms (s_j's) are available, equation (3) can be estimated.[3] The estimating equation would be of the form,

$$(4)\qquad Y_i = Y_n + (Y_1 - Y_n)s_{1i} + (Y_2 - Y_n)s_{2i} + \ldots + (Y_{n-1} - Y_n)s_{n-1\cdot i} + v_i,$$

where i stands for the district and v is a disturbance term which has zero mean, uniform variance, and which is uncorrelated with the independent variables. It will be noticed immediately that the parameters of equation (4) are none other than the productivities of different size classes of farms.

One problem with equation (4) in its present form is that, since the productivities enter the equation as coefficients, the productivity of a size class is assumed to be identical for all the districts in the

[3] The equation can be estimated only under the assumption of an i.i.d. error term. The addition of an error term to an identity such as that in equation (3) is difficult to justify on theoretical grounds, but is needed as an empirical expedient.

sample. This assumption is too restrictive, especially when dealing with an all-India sample of districts. However, if the productivity coefficients themselves are expressed as functions of some other variable, we can have the productivity of the same size class varying from district to district. In our case, we can let this variable be the level of technical change experienced by a district, so that the hypothesis of the inverse relationship weakening with technical change can also be tested simultaneously.

The estimating equations are then of the form,

$$(5)\quad Y_i = Y_{ni} + (Y_{1i} - Y_{ni})s_{1i} + (Y_{2i} - Y_{ni})s_{2i} + \ldots + (Y_{n-1\cdot i} - Y_{ni})s_{n-1\cdot i} + v_i,$$

$$(6)\quad Y_{ki} = a_k + b_k I_i,$$

where $k = 1, 2, \ldots, n$, and I_i is the variable inducing a continuous shift in the productivities of each size class of farms. Equations (5) and (6) collapse into a single equation, estimable by ordinary least squares:

$$(7)\quad Y_i = a_n + b_n I_i + (a_1 - a_n)s_{1i} + (b_1 - b_n)s_{1i}I_i + (a_2 - a_n)s_{2i} + (b_2 - b_n)s_{2i}I_i + \ldots + (a_{n-1} - a_n)s_{n-1\cdot i} + (b_{n-1} - b_n)s_{n-1\cdot i}I_i + v_i.$$

Once equation (7) is estimated and the a and b coefficients obtained, we can apply the formula in equation (6) to get the technology-specific productivities of each size class of farms.

Application

Data for 272 districts have been used to estimate equation (7).[4] The data are for the agricultural year 1970–71, except in the case of average district productivity per hectare, which is averaged over three years (1969–70, 1970–71, and 1971–72) to eliminate short-term fluctuations arising because of abnormal weather. In calculating district output, constant all-India prices have been used to value each crop.

The variables used in the analysis are defined, and their means and standard deviations reported, in table 1. Two things will be noticed from this table: first, size classes have been defined in terms of size quintiles of farms. This circumvents the problem of comparability of acre- or hectare-defined farm sizes across heterogenous regions, and allows us to define categories that transcend regional boundaries.

Second, average fertilizer application per hectare has been used as a proxy for technical change in agriculture. This is because chemical fertilizers, along with the high-yielding varieties (HYVs) of seeds, have been mainly responsible for the vast increases in yields that have come to be known as the Green Revolution. Because of the very high degree of complementarity between HYV seeds, fertilizers, and irrigation, any one, rather than a composite index of all, of these factors can be used as a proxy for technical progress.

The OLS regression results are reported in table 2. Using the formula in equation (6), predicted group- and technology-specific productivities have been computed from the raw regression coefficients. These are shown in table 3. Additionally, tests of significance on linear combinations of the estimated coefficients have been performed to test hypotheses of no difference between the productivities of various groups of farms operating at the same level of technology. The results of these tests are also reported in table 3.

The results tend to confirm the two hypotheses mentioned earlier. At the level of technology represented by no fertilizer use (shown in the first row of table 3), the smallest two quintiles of farms have significantly higher yields per hectare than the medium and the large farms. On the other hand, at higher levels of technology (shown in the lower rows of table 3), the large farm sector is significantly more productive than the medium farm sector, which in turn is significantly more productive than the small farm sector. Not surprisingly, each size-group of farms shows greater yields per

[4] The data have been compiled from a number of aggregate data sources, including the various state reports of the *Agricultural Census of India 1970–71* (for data on the size distribution of holdings), a joint Nehru University-Planning Commission study entitled *Foodgrains Growth: A Districtwise Study* (for data on average district productivities), and *Fertilizer Statistics 1972* (for data on fertilizer use).

Table 1. Variable Dictionary and Sample Means, Indian Districts, 1970–71

Variables	Definition	Mean	Standard Deviation
OUTPGH	Gross value of output (of 22 major crops valued at constant prices) per hectare of cropped area	1,005.99	491.73
*SHARE*12	Share of smallest two quintiles of farms in total cultivated area	0.095	0.039
*SHARE*34	Share of third and fourth quintiles of farms in total cultivated area	0.330	0.059
*SHARE*5	Share of largest quintile of farms in total cultivated area	0.575	0.077
FERTPGH	Per-hectare application of all chemical fertilizers (in kilograms)	18.6	21.4

Table 2. OLS Regression Coefficients, Indian Districts, 1970–71 Dependent Variable: OUTPGH

NOTE: All variables have been defined in table 1.

hectare at higher levels of agricultural technology than at lower levels, confirming the expectation that technical change in agriculture dramatically increases the productivity of land. The fact that the productivity of the large farm sector increases by a wider margin than that of the small farm sector suggests that the gains of technological change accrue disproportionately to the former.

Conclusion

In this paper, regional data from India have been used to test the hypotheses that (*a*) the small farm sector as a whole enjoys higher yields per unit of land than the large farm sector in Indian agriculture, but (*b*) this yield-advantage of the small farm sector diminishes, and in fact even reverses, with technical change (primarily of the Green Revolution type) in agriculture. The data seem to confirm both the hypotheses.

Unfortunately, the data cannot be used to explain the change in the relative yields of the small farm sector with technical progress. On the basis of prior judgment and results from other studies, it seems that the explanation lies in the reduced importance of labor (which is possessed in abundance by the small farms) and the increased importance of cash inputs like fertilizer and improved seeds (which being credit-intensive cannot be afforded by the small farms) in determining land productivity in the post-Green Revolution period.

The policy implications of these findings are obvious. The argument that a redistribution of land from the large to the small farms will increase average yields and hence agricultural output cannot be extended to an agriculture experiencing technical change. Instead, policies which allow small farms to obtain credit easily and thus use the new agricultural technology should be stressed for productivity growth.

International Farm Prices and the Social Cost of Cheap Food Policies: Comment

Yoav Kislev

The purpose of this note is to show that the prices which Peterson computed for his recent paper also can be viewed as effective exchange rates. Deviations from the world relative price system in agriculture are usually the result of market intervention, taxes, or subsidies. Such distortions, whether they are the result of domestic or of trade policies, can be viewed as distortions in effective exchange rates. For international comparisons, the exchange rate view is, analytically and conceptually, more general and convenient.

Peterson's wheat equivalent price, $\hat{p}_i$ for the commodity i, is defined as

$$\hat{p}_i = p_i(\bar{p}_w/\bar{p}_i), \tag{1}$$

where p_i is the local currency farm price of the commodity i; $\bar{p}_i$ and $\bar{p}_w$ are, respectively, the world dollar price of the commodity and wheat. The prices $\hat{p}_i$ are expressed in local currencies and calculated for each commodity in every country (the country index is omitted here).

The aggregate overall average output price for each country is

$$P = \Sigma \hat{p}_i w_i, \tag{2}$$

where the weights are $w_i = (\bar{p}_i q_i)/(\Sigma \bar{p}_i q_i)$, with q_i being the quantity of commodity i.

Equation (2) can be rewritten as

$$\begin{aligned} P &= \bar{p}_w \Sigma (p_i/\bar{p}_i) w_i, \\ &= \bar{p}_w E \end{aligned} \tag{2'}$$

The dimension of E is local currency per dollar. Thus, it is the effective farm product exchange rate. E is the value in local currency of the quantity of a composite bundle of domestic farm products that will fetch one dollar on world markets.

Peterson defined the real price as P/p_f—output price divided by the country's local price of fertilizers. Comparing countries, we are interested in price differences or ratios of real prices. In such ratios, world prices cancel out, and we can write the real prices as

$$\begin{aligned} R &= (\bar{p}_f/\bar{p}_w)(P/p_f), \\ &= E\,\frac{\bar{p}_f}{p_f}, \end{aligned} \tag{3}$$

where $\bar{p}_f$ is the world dollar price of fertilizers. If one views, with Peterson, cross-country differences in fertilizer prices as representing differences in the average price of production factors, then $p_f/\bar{p}_f$ is the effective exchange rate in the farm input market.

In equation (3), R explicitly reflects the agricultural exchange rate. Differences between countries in their R values are due to effective exchange rate distortions in the product and in the factor markets. Therefore, Peterson's supply equation can be interpreted more generally as a response function to effective exchange rate distortions. These distortions reflect market interventions stemming from both domestic and trade policies.

The Value of Unrealized Farm Land Capital Gains: Comment

Ross G. Drynan and Ian D. Hodge

Plaxico and Kletke (PK) presented three alternative models for valuing farmland capital gains. Their first model assessed the present value of anticipated capital gains, assuming that they have value only when the asset is sold. Their second model viewed the value of unrealized capital gains as equivalent to a tax-deferred income stream with the tax being paid at capital gains rates either when the property is sold or at the end of the planning horizon. Their third model assessed the value of the capital gains as an equity base for further credit.

Dunford has criticized PK's formulations, especially their second model. However, his alternative model perpetuates several errors made by PK. Other errors made by PK led them to an important conclusion about tax rate effects, which conflicts with conventional wisdom. In this comment we correct the models for these errors and offer some further thoughts on the assessment of the value of farmland capital gains.

Dunford correctly comments that, "because the capital gains on the farmland are not actually realized until year n, it is necessary to borrow for additional investments." The value of unrealized capital gains will depend on how the increased equity base is used in borrowing more funds and how the borrowed funds are invested. There are two possibilities. One is that each year's capital gain is used as a basis for a one-year investment. Second, the gain can be the basis of an investment lasting for the whole planning horizon. The latter is equivalent to using the total accumulated value of capital gains each year as an equity base for an investment lasting one year. These two possibilities conform to Dunford's equations (2′) and (3), respectively, equation (3) being identical to PK's third model. Since the first of these alternatives appears distinctly inferior, we concentrate on the latter.

What these authors have failed to note is that it is only possible to use an unrealized capital gain as an equity base for an investment in periods after the gain occurs. All the models suggested by PK and Dunford for valuing unrealized capital gains imply that the farmland owner can borrow at the start of each year against the expected capital gain in that year. This is clearly not tenable and leads to an overestimation of the gains of about 5%.

PK err further in the way in which they include tax and inflation in their models. The present value of any future cash sum can be calculated either by discounting the nominal sum with a nominal discount rate to year 0, or by discounting the real value, measured in year 0 dollars, of the cash sum by the real discount rate. Both methods necessarily lead to the same present value. For example, a future sum S_n, when discounted at a nominal rate N, has a present value

$$PV = S_n/(1 + N)^n.$$

With discounting in real terms, the future sum becomes $S_n/(1 + Z)^n$, where Z is the inflation rate. The real discount rate R is directly related to the nominal rate, and is defined by

$$1 + R = (1 + N)/(1 + Z).$$

The present value is

$$PV = S_n/[(1 + Z)^n(1 + R)^n].$$

When substitution is made for $(1 + R)$, all factors involving Z cancel, producing the nominal analysis formula. Inflation may nevertheless still affect the present value through any effect it has on the nominal discount rate. However, as argued by Dunford, it is only if the real discount rate is used in the formula that the inflation rate will also appear.

PK include tax explicitly in their formula, effectively defining $D(1 - T)$ as an after-tax discount rate. With D defined as a real discount rate, this tax adjustment is appropriate only if D is a before-tax real opportunity cost and if tax is levied on real income. When taxes are levied on nominal income, as is usual, the real after-tax opportunity cost or discount rate R is defined by

$$1 + R = [1 + N(1 - T)]/(1 + Z).$$

When D is not simply the before-tax opportunity cost, the effect of tax on the discount rate is unclear and unlikely to be the simple proportionate reduction assumed.

It is our contention that PK's models would best be amended by deleting all explicit reference to the inflation rate, and by defining D as the nominal before-tax opportunity cost. Their third model then becomes

Ross Drynan and Ian Hodge are lecturers in the Department of Agriculture, University of Queensland.

Table 1. Estimates of the Value of Capital Gain for Plaxico and Kletke's Models

	Rate of Land Increase							
	5%				10%			
	Tax Rate							
	15%		40%		15%		40%	
	Discount Rate							
	12%	18%	12%	18%	12%	18%	12%	18%
10-Year planning horizon								
Model I	22024	14009	25102	18041	55814	35503	63615	45720
Model III	25286	21187	27899	24692	63231	51723	69997	60833
20-Year planning horizon								
Model I	21921	8869	32926	17007	75940	30726	114067	58920
Model III	30892	24612	41925	34775	100014	71648	138669	106417

Note: 9% interest rate is assumed.

$$(1)\quad V_2 = \sum_{i=2}^{n} \frac{(P_{i-1} - P_o)(B)(D - r)(1 - T)}{[1 + D(1 - T)]^i} + \frac{(P_n - P_o)(1 - T_c)}{[1 + D(1 - T)]^n},$$

where all other terms retain the meanings given by PK.

PK arrived at a false conclusion about the effect of marginal tax rates on an individual's competitive position in the land market. This can be measured by the individual's present value of land investment. The value of capital gains does not directly measure this present value. However, if two individuals are equally competitive in the absence of capital gains, then, when capital gains do occur, the individual with the greater value of capital gains is necessarily more competitive. We have no quarrel with the assumption of initial equality implicit in PK's comparisons. But they have made a critical error in their calculation of the present values of capital gains with high tax rates. They have, in fact, failed to adjust their discount rate for the higher tax rate (40%). PK's reported calculations show a consistent pattern of lower values for this higher marginal tax rate, suggesting the low rate individual is advantaged by capital gains, a result which conflicts with conventional wisdom about this matter. However, when corrected, the values are in fact consistently higher than those for the lower (15%) marginal tax rate, implying a competitive advantage for the individual with the higher marginal tax rate. We report the corrected values of capital gains in table 1.

PK add a further source of confusion in their note to table 2, where they indicate that they have incorporated "two inflation rates." This conflicts with their earlier comment that "the impact of inflation is ignored" (p. 328). The two inflation rates presumably refer to the two rates of land price increase which they have used.

A number of other issues arise out of PK's paper and Dunford's comment. Is it sensible to isolate and separately value the capital gains component from other components of land investment? What are reasonable *ceteris paribus* conditions for valuing capital gains? Is it, for example, reasonable to assume that the rent earned by land is independent of capital gains? Can the discount rate and the initial price P_0 be assumed to be unaffected by capital gains? If not, the valuation models presented so far will need considerably more development. These are complicated issues deserving greater attention than they have received so far.

The Value of Unrealized Farm Land Capital Gains: Reply

James S. Plaxico and Darrel D. Kletke

The major thrust of our original paper was an exploration of alternative approaches to the evaluation of unrealized farm land capital gains (1979). Drynan and Hodge (DH) raise several important questions regarding the formulation of our Model III and point out an error in some of the computations. Unfortunately, DH, like Dunford, did not properly identify the essential difference in the conceptual bases of our Models II and III. Thus, DH do not comment on the central ideas of our paper. Our Model II is, in effect, a wealth approach to value, while our Model III is an income approach to value. This distinction is emphasized in our response to the Dunford comment (1980).

Our models are discrete on an annual basis. DH correctly point out a model error which allows capital gains to be utilized in the year of occurrence. However, gains are continuous, and although we overstate benefits, the error is not as significant as implied by DH.

Tax Adjustments

Our discount rate (D) is in real, not nominal, terms and is the opportunity cost of capital to the individual (firm) for assets that are comparable in terms of risk and uncertainty. D is a required internal rate of return (RIRR) specified by the investor and should not be confused with the average rate of return experienced by landowners. DH correctly point out that taxes are levied on nominal, not real, income. However, in our models, all tax payment adjustments are made in the income (value) stream components. That is, we tax adjust a flow of nominal income (value). We tax adjust D in the denominator only to obtain an after-tax, real discount rate (RIRR). We, in turn, convert this to a nominal rate to discount a nominal stream of benefits.

Upon reflection, precipitated by DH comments, we conclude that D should be defined in after-tax terms in lieu of tax adjusting a pre-tax D. This would permit direct comparison of the impact of the tax rate for a given real after-tax discount rate. Models are constructed to reflect (simulate) perceived reality. We suspect that investors think in terms of a real after-tax RIRR, not in terms of a before-tax RIRR. If this is in fact the case, it is not correct to interpret the results in our table 2, nor those in DH table 1, as a proper reflection of the impact of the tax rate for a given discount rate. This is the case because both data sets reflect the implications of the tax rate given the same pre-tax, not after-tax, discount rate.

Capital Gain Values, Tax Rates, and Inflation

The impact of the marginal tax rate for present values and bidding potentials is clearly an important issue. Harris and Nehring examined the impact of the marginal tax rate on the bidding potential of prospective buyers. Their conclusion, as summarized by Adams (p. 540) is: ". . . note that their present value formula implies that individual valuations decrease as the marginal income tax rate rises and high income persons *ceteris paribus* bid less for farmland than do persons in lower tax brackets" (p. 540).

Adams showed that for an infinite planning horizon, the value of an income stream is independent of the tax rate, while for a finite period, a higher tax rate results in a lower bid or value. Adams did not consider the impact of tax rate on the value of capital gains. Lee and Rask (table 2), using a model similar to our Model I, report results which compare the impact of the marginal tax rate on bidding potential. Their results suggest a higher bidding potential for a zero marginal tax situation than for a 40% rate as well as a higher bidding potential for a zero capital gain rate than for a 25% rate. Ling has further examined the Harris and Nehring model and has suggested that the net effect of the marginal tax rate is uncertain, lacking information regarding the prospective buyers utility function. Finally, Ling (p. 846) concludes that the effects of a change in the marginal tax rate on farmland bid prices is far more complex than Adams has asserted.

Our model is deterministic, and a simple assumption that utility is a direct function of present values is implicit. DH are correct in stating that we made a clerical error in computing our table 2 by failing to adjust the discount rate for the higher (40%) tax bracket assumption. That is, we adjusted all rates for a 15% tax rate. This led to the conclusion that, other things equal, higher capital gain values are associated with lower income tax rates. The DH

James S. Plaxico is State Director, Oklahoma ASCS, U.S. Department of Agriculture; Darrel Kletke is a professor of agricultural economics, Oklahoma State University.

Oklahoma Agricultural Experiment Station Journal Article No. J3909.

computed numbers show the opposite. We have recomputed our table 2, defining D as a real after-tax rate. Again, other things equal, higher capital gains values are associated with lower tax rates. Thus, it seems appropriate to conclude that (*a*) for equal after-tax discount rates, other things equal, higher capital gains values are associated with lower tax rates, (*b*) for equal before-tax discount rates, other things equal, higher capital gains values are associated with higher tax rates. It is our conclusion that the appropriate analysis is the impact of the tax rate given equal after-tax discount rates.

DH contend that our models could be improved by deleting explicit reference to the inflation rate and by defining D in nominal terms. We elected to work in terms of real discount rates adjusted for inflation in order to examine the implications of different discount rates and different inflation rates.

Summary

In summary, the DH comments caused us to rethink our formulations. We sincerely appreciate their important contributions. We also are pleased to have an opportunity to extend, adjust, and clarify our arguments. DH question the relevance of evaluating capital gains in isolation. Much remains to be done in the area. However, a modest effort to incorporate capital gains models into a more general land value model is contained in Kletke and Plaxico (1978). The model has been presented as a time share computer algorithm, giving the user control of the relevant variables (Kletke and Plaxico 1979). Analyses based on the general land-value model show that meaningful bidding potential estimates must reflect cash flow constraints including possible cash flow deficits.

prime rate) return on assets in both food processing and in all manufacturing has fallen decidedly over the past twenty-five years (table 1A). During the past decade, return on assets was below the prime rate for both all-manufacturing and food processing. Further, the return on assets in all manufacturing was consistently above the return on assets in food processing.

The opportunity cost of equity capital is several percentage points above the opportunity cost of loan capital (Malkiel). However, again for illustrative purposes, we will use the prime rate to adjust return on equity. The adjusted return on equity in food processing declined by around 10% between the 1950s and 1970s, but did increase by around 12% between the 1960s and 1970s (table 1B). Certainly there was not a real "50% increase in return on equity over the past quarter century" (Parker and Connor, p. 627). The relatively constant, or modestly decreasing, return on equity was obtained with substantially increased risks due to increased leverage through time.

With decreasing real return on assets and constant, or modestly decreasing, return on equity, the net social costs of profits in the food industry undoubtedly have declined significantly over the past thirty years.

Parker and Connor's choice of the year 1975 as the time period was fortuitous for their hypothesis, because the undeflated profit levels they used were among the highest in thirty years. However, real or deflated profit levels were among the lowest in thirty years.

In their empirical analysis, Parker and Connor apply three different approaches to calculating consumer loss caused by the operation of the U.S. food-manufacturing industries. We will look at each in turn in terms of underlying assumptions, methodology, and empirical estimates.

The loss-components estimates are based on an "iffy" and "subjective" method used by Scherer. Explicitly assumed is that "a competitive profit rate was for an industry with 40% four-firm concentration, equal market shares among the top four and a media advertising-to-sales ratio of .05%" (Parker and Connor, p. 630). All of manufacturing, according to Parker and Connor has a weighted four-firm concentration ratio (CR-4) of 44%, or 10% above the assumed competitive standard of 40%. However, food manufacturing's CR-4 is 52%, which is 30% above the competitive standard, or three times the rest of manufacturing. Since Scherer found an X-inefficiency loss of 3.1% of value added for all manufacturing, Parker and Connor assumed that the X-inefficiency loss in food manufacturing was 9.3% of valued added (see their table 1, type of loss 3).

It is doubtful that X-inefficiency losses increase linearly as their method implies when CR-4 for an industry increases. For example, applying this method to the data for twenty major industry groups in the original working paper on which the Parker and Connor *Journal* article was based, yields X-inefficiency type three losses of 7.3%, a serious overestimate compared to Scherer's original 3.1% estimate. In addition, their results are highly sensitive to the competitive standard they assumed for CR-4. If the true value of the competitive CR-4 lay within plus or minus three percentage points of their point estimate, calculated consumer loss from

X-inefficiency could range from \$3,200 to \$13,414 million, versus the Parker and Connor estimate of \$4,480 million. Further, as the competitive CR-4 approaches 44%, their multiplicand approaches infinity, a grossly different result from the one they have arbitrarily chosen (figure 1).

In the price-cost margin approach to measuring consumer loss, price-cost margins (PCMs) are regressed on a measure of concentration (CR-4) and other variables. The authors then use the resulting equation to predict what PCM would be for each industry at their assumed competitive level of concentration, CR-4 = 40%, and with all other variables held constant. The differences between the actual PCM and this projection is then considered the consumer overcharge.

The authors in fact present three alternative equations based on the original Collins-Preston model and claim to derive reassurance from the closeness of the results. For the first two equations which included a quadratic term for CR-4, it was possible to estimate that level of CR-4 which would minimize PCM. For equation (1) it was 19.6%; for equation (2) it was 195.4% (clearly a nonsensical result). Even in equation (1), only the squared CR-4 term was significant at the 5% level. When we checked the sensitivity of the results to errors in estimates of the coefficients we found that if the true value of the coefficients of the CR-4 variable lay within plus or minus one standard error of the reported point estimates, then the true value of the lowest PCM could occur for a range of CR-4 from 4.7% to 46.3%. Thus the findings appear not to be robust.

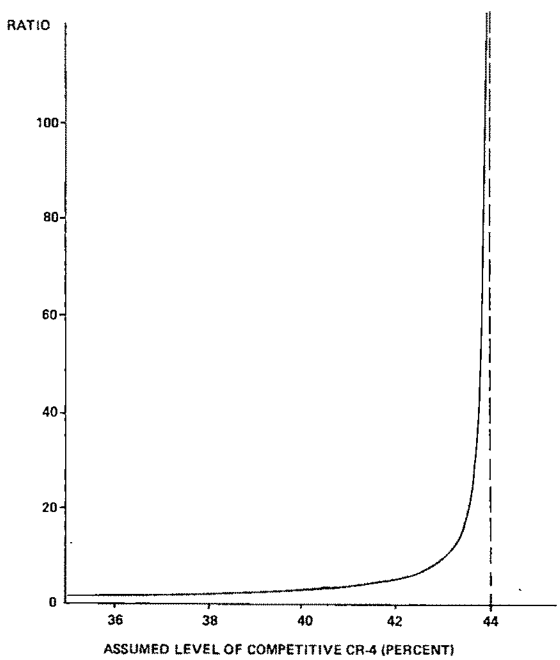

Figure 1. Estimated ratio of excess concentration in food manufacturing to excess concentration in all-manufacturing, using Parker and Connor method for different assumed levels of competitive CR-4

Equation (3) had no nonlinear term for CR-4, but the inclusion of linear and nonlinear variables for advertising as a percentage of sales of the four largest firms in each industry (ADS-4) enables us to estimate that PCM is maximized when ADS-4 equals 11%, twenty-two times the competitive value of ADS-4 used by Parker and Connor in estimating overcharges. Thus the arbitrary competitive value of ADS-4 assumed by Parker and Connor appears low. Only six of forty-one industries exceeded half that maximizing level in 1975, and only fourteen exceeded one quarter that level. Thus we are left with a paradox—if advertising is the key to monopoly profits, why do not food manufacturers spend proportionately more on advertising?

Parker and Connor apply sensitivity analysis to the choice of the competitive level of CR-4 in their PCM analysis, but not the variation of other estimated coefficients which would have proved more susceptible to small changes in value.

Parker and Connor's third approach to measuring consumer loss, which they call their "National Brand—Private Label Price Difference Estimate," assumes that private label merchandise is identical in quality to manufacturer brand merchandise. "Prices of food-chain private labels are considered to approximate competitive prices; the amounts by which manufacturer brand prices exceed private label prices for the same items and which can be attributed to departures from perfect competition are considered to be estimates of monopoly overcharges" (p. 633). As justification for this approach, Parker and Connor assume "that national brands sell at premiums which manufactures set in accordance with the strength of preference created by advertising and other promotion" (p. 634).

The authors ignore the large body of literature on quality competition per se (for a starting point, see Abbott). They ignore the problems of interpretation of physical quality measures. For example, Jafri and Lifferth's 1977 study found an average viscosity of national brand canned applesauce in terms of centimeters of flow per unit of time of 4.6917 versus 5.4167 for private brands. But this begs the question whether the highest quality would be represented by a viscosity measure above, below, or between those levels. Because most products possess a number of physical characteristics, the problem of determining "best" quality or best value for money becomes extremely complex, if determinate at all except in terms of consumer responses in the market. Finally, the identification of quality in terms of physical properties of a product ignores the role of consumer perceptions of quality in determining purchase and consumption behavior and the more fundamental philosophical question whether or not products are different because consumers perceive them to be different.

The set of assumptions put forward by the authors is only one, and by no means the most plausible, explanation of the relationship between private label and manufacturer brand merchandise. For example, Handy and Padberg report that what they call "core distributors," the ten largest retail food chains, dominate both manufacture and sale of private-label products. Core manufacturers, defined as the 100 largest food processors, dominate the manufacture and sale of specialized consumer products. On the other hand, fringe (all other) distributors not in the core group specialize in more effective performance at the retail level, while fringe processors "rely heavily on the private label programs of wholesalers and retailers for market outlets" (p. 185).

These two major foci of power seek consumer attention and patronage in different ways. "The manufacturing oligopoly stresses product development and is clearly more adept at this function than the distribution oligopoly. The latter is able to dominate the terms of trade for standard products and merchandise them to the public with an economy emphasis through extensive private-label programs" (Handy and Padberg, p. 184). "Oligopoly core manufacturers tend to work most directly with fringe distributors. This combination constitutes a channel that emphasizes innovation and progress as regards the character of the product and services . . . Oligopoly core distributors tend to emphasize private label programs; hence they are best served by the fringe processors" (p. 183).

Thus, a firm's strategy on manufacture or distribution of branded or private label products can be viewed as a rational response to its desire for survival and growth in its existing competitive environment. In this context, it is difficult to argue that private-label prices approximate the competitive norm, and that the differences between national brand and private-label prices are an unambiguous basis for measuring overcharges due to monopoly. Indeed, it seems conceptually inappropriate to explain differences between brand and private-label price as due to the structure of the food-processing industry without taking account of the structure of retailing and the interaction between processors and retailers.

However, Parker and Connor choose to do so. Essentially, they explain the price difference between branded and private label items of the same product in terms of variables used in their first two approaches, four-firm concentration, advertising, a geographic-market index, and a variable for industry growth, with the addition of three further variables to represent volume of sales by product class (*LNSIZE*), number of firms (*LNFIRMS*) and net imports (*NETIMP*). They used no less than three separate advertising variables and, in all, ten explanatory variables. Clearly, their final functional form was based on ad hoc rationalizations, rather than on a tested, coherent theory of the process being modeled. Thus, one may question the appropriateness of the final equation chosen. For example, if CR-4 had been represented by a linear term and ADS-4 by a quadratic term, as in Parker and Connor's equation (3), would signs, magnitudes, or significance of coefficients have been altered? And if the variables, *LNSIZE*, *LNFIRMS*, and *NETIMP* help to explain monopolistic price differences (*DIFF*), should they not also have been used to explain monopolistic price cost margins (*PCM*) in equation (3)?

Having presented three separate approaches to measurement of consumer loss, the final plank in Parker and Connor's argument is that "the extent of convergence of all three essentially independent estimates gives strength to the conclusion that consumer loss due to monopoly in the U.S. food-manufacturing industries in 1975 was at least $10 billion, but possibly as high as $15 billion" (p. 637) [or from 1.9 to 2.9 times total profits in the industry for 1975].[1] However, we have shown that their loss components estimate explodes if the competitive CR-4 approaches 44% and varies widely for small deviations around their assumption that CR-4 equals 40%. Their estimate based on the price-cost margin method is sensitive to variance in the estimated parameters. Their national brand-private label price difference estimate ignores the structural interaction of food processors and retailers and relies on a functional form indistinguishable from thousands of others, equally plausible. Thus, convergence rests on specific arbitrary assumptions chosen by the authors and not on the industry's unique "monopolistic" characteristics.

The authors call for stepped-up antitrust activity including limiting advertising, stricter policies on product extension mergers, and even divestiture of physical assets of leading firms and compulsory licensing of major trademarks. This recommendation to alter significantly the structure of the food-manufacturing industries is not justified by the data presented. Even if the analyses were based on solidly realistic assumptions and if the methodologies were sound, precise, and unquestionable, their recommendations would not necessarily follow. The authors ignore any possible losses in efficiency from restructuring. These efficiencies are an integral part of structure considerations (Greig). For example, in comparing alternative industrial structures McGee states, "A proper standard involves efficiency considerations . . . it is a question of fact whether efficiencies of large firms have been or will be generated, relative to other industrial structures" (p. 135); and Weston argues, "In summary, recent evidence runs against the view that concentration in the U.S. is higher than need be for efficiency" (p. 626). Parker and Connor present no evidence that the social returns from their reorgani-

[1] Department of Commerce data suggest total corporate profits in food processing in 1975 to be around $5.2 billion, while Internal Revenue Service data suggest corporate profits to be around $4.1 billion.

zation of food manufacturing industries would be greater than the social cost.

Parker and Connor have made an heroic attempt to quantify an elusive concept. Their approaches will be valuable to future researchers who keep in mind the limitations we have highlighted. In addition, while researchers undoubtedly will continue to study whether or not there is consumer loss due to market imperfections in food manufacturing, we have tried to show that researchers ought also to be concerned about the falling real return on assets and on equity in all U.S. manufacturing and in food manufacturing.

Estimates of Consumer Loss Due to Monopoly in the U.S. Food-Manufacturing Industries: Comment

J. Bruce Bullock

In a paper published in the November 1979, issue of the *American Journal of Agricultural Economics*, Parker and Connor conclude "that consumer loss due to monopoly in the U.S. food-manufacturing industries in 1975 was at least $10 billion, but possibly as high as $15 billion" (p. 637). The authors suggest that their findings provide justification for expanding the budgets of U.S. antitrust agencies and for restructuring the industry.

Parker and Connor (PC) have provided only part of the information required to draw these conclusions. Therefore, the results of their study do not provide justification for either expanding the antitrust agencies or restructuring the U.S. food-processing industry. Indeed, it is quite possible that restructuring the industry toward a more atomistic structure would be contrary to the public interest. The relevant question is not, how much monopoly profit exists in the food-processing industry? Rather, the relevant questions are: (*a*) does an alternative industry structure exist that will provide more net consumer welfare with no increase in resource use? and (*b*) how can the change to the "preferred" structure be accomplished and what will be the cost? Parker and Connor have not answered these questions.

The monopoly overcharge rectangle as defined by PC is illustrated in figure 1, assuming a linear demand curve DD and constant average cost curves; C_a represents the cost curve if the industry has an atomistic structure. Parker and Connor postulate that the costs of firms in the oligopolistically structured industry (C_1) are above the costs that would exist in an atomistically structured industry. The monopoly price P_1 thus extracts monopoly overcharges of P_1AFC_a from customers. "Just how much of the overcharge rectangle P_1AFC_a is an income gain to the monopolistic depends on how much higher the monopolist's average costs (C_1) are compared to the competitive level C_a" (Parker and Connor, p. 628).

What evidence do we have that the monopolists' costs are higher than the costs of more atomistically sized firms? Changes in the number and size of firms in the industry over the past twenty-five years strongly indicate that the costs of these larger firms are lower than the costs of the firms they replaced. How could higher-cost firms have replaced lower-cost firms? The current structure could have evolved only because the costs of the larger firms are below those of smaller firms that exited the industry. Apparently, the oligopolistic firms provided consumers with lower priced (or perhaps higher quality) products—not just on a short-term "predatory" basis, but over a prolonged period of time under wide-ranging economic conditions; to argue that the costs of the oligopolistic firms are higher than the costs that would exist in a more atomistic structure (for the same quality product) is to ignore the economic reality of what has happened in the past twenty-five years. It does not matter whether the firms grew through internal expansion or through acquisition. The fact remains that the larger firms could survive while smaller firms exited the industry only if the costs of the larger firms are lower than costs of smaller firms.

The observed structural changes over the past twenty-five years suggest an alternative analytical framework may be more appropriate for evaluating the social desirability of the current structure of the U.S. food industry. As noted above, evidence provided by the marketplace strongly suggests that the costs for the oligopolistic industry are below the costs that would exist in a more atomistic industry, say, level C_2. The oligopolistic market price in this situation will be somewhere between C_2 and C_a, for example, P_2. Monopoly rents in this situation are therefore represented by the area P_2HJC_2 in figure 1. This is the area which PC estimated to have been $12.5 billion in 1975 (midpoint of their range). While $12.5 billion sounds like a lot of money, it amounts to only about $1 per person per week—hardly more than rounding error in the consumer's food budget.

Greig points out that there are social costs of atomistic competition. "Because the atomistic markets approach the 'perfect' markets in numbers and size of firms, some seem to assume that atomistic markets operate with few or no social costs. However, if the costs to society of imperfections in the atomistic markets were compared to imperfections in the segment having market power, then by far the greater social costs would be in atomistic markets. The lack of knowledge of potential supplies and potential demands, unnecessary risk and uncertainty, lack of knowledge and lack of optimum scale, excess capacity, mislocations, cross-

Journal Article No. 3901, Oklahoma Agricultural Experiment

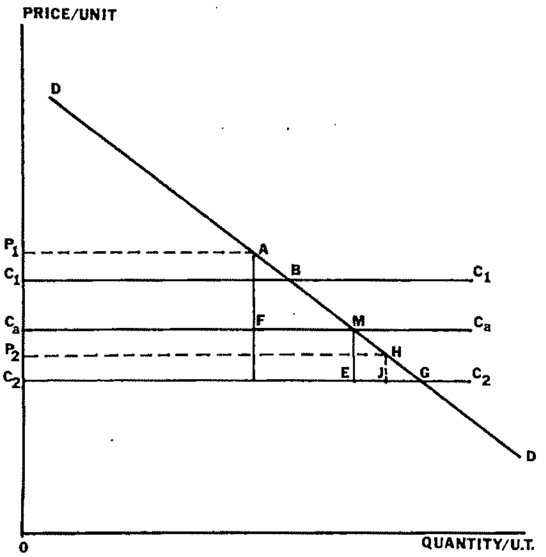

Figure 1. Illustration of Possible Impacts on Consumer Welfare: Oligopolistic vs Atomistic Industry Structure

food markets considerably outweigh the social cost of market power" (p. 27).

The social cost of atomistic competition is represented by area C_aC_2JHM in figure 1 ignoring (as PC did) the resource allocation dimension of monopoly pricing.[1] (Note that the allocative inefficiencies under an atomistic structure [*MGE*] are larger than under the oligopolistic structure [*HJG*].) Because the social costs of atomistic competition exceed monopoly rents in this situation, consumers are better off with an oligopolistic structure than with an atomistic industry structure. This will be the case any time that production costs of the oligopolistic structure are below those that would exist in an atomistic structure, and monopoly powers are not exercised to the point that a price above C_a is extracted from consumers. The economic incentive of oligopolists will be to charge a price below C_a so as not to attract competition. Moreover, rivalry between oligopoly firms will keep returns competitive with other segments of the economy. How can monopoly profits exist if resources earn no more than their opportunity cost? Thus, the $12.5 billion "monopoly overcharge" estimated by PC may be a quite acceptable price to pay for the consumer benefits (area C_aC_2JHM minus the area P_2HJC_2 in figure 1) generated by an industry structure that enables firms to take advantage of economies of size, achieve better coordination, reduce risk, and make investments in new product development.

Unfortunately, there are several value judgments expressed in the PC paper that detract from its usefulness as an objective and scholarly analysis. For example, in trying to convince the reader that monopoly firms have higher costs than competitive firms, Parker and Connor state that "monopoly firms often allow managerial withdrawals in the form of fancy offices, corporate jets, and other inessential perquisites" (p. 628). This leaves the authors in the untenable position of trying to answer the following questions: What distinguishes a "fancy" office from an adequate-but-not-fancy office? Are corporate jets always unsound business investments? What is the difference between an inessential and an essential perquisite? For example, is the civil service retirement system for government employees (such as Parker and Connor) an essential or inessential perquisite?

Parker and Connor mistakenly conclude that because "monopolists do not have as strong incentives to minimize their costs of products as do competitive firms" (p. 628) the production costs of oligopoly firms will be higher than the costs of firms in an atomistic industry structure. Arguments that costs of oligopoly firms could be lower than they currently are, are perhaps true. However, such arguments are irrelevant for purposes of making judgments about the social desirability of alternative industry structures. In an economy such as ours where there are enormous economies of firm size, the production costs of oligopolistic firms may be below the costs of firms in an atomistic structure—even if the oligopolists do not produce at minimum costs.

PC place heavy emphasis on the social costs associated with oligopolistic firms use of advertising funds. They state that advertising "expenditure levels and content are not made in accordance with consumer preference; rather thay are chosen by companies to maximize advertising effectiveness. Although advertising expenditures may be efficient for this purpose, they are likely very inefficient in producing social benefits" (p. 629). Apparently PC use the term "social benefits" of advertising to refer to the entertainment value of programs sponsored by advertising expenditures. Their conclusion about the inefficiency in use of these funds seems to be at odds with reality. Presumably, consumers watch television shows they like best. Advertising agencies and the networks pay close attention to program ratings reflecting the number of viewers. Moreover, per-minute advertising rates vary directly with the current and/or projected ratings of a program. Such a pricing and advertising expenditure allocation system appears to be quite consistent with the use of advertisement funds to produce social benefits as well as maximization of

[1] A reviewer of this comment points out that this type of geometry is applicable only when one is dealing with homogenous and competing products. This points out the problems—perhaps the complete fallacy—of applying the concepts if monopoly profits to a multiproduct and product-differentiated industry such as food manufacturing. However, such a distortion is necessary if we are to address questions about the social desirability of the structure of these types of industries. The costs reflected in the cost curves of figure 1 are the total set of costs of production, product differentiation, and all other costs associated with operation of firms in the industry.

expected return on advertisement expenditures. Therefore, the production of social benefits with advertisement expenditures is inefficient (as suggested by PC) only if television viewers are incapable of determining what they enjoy watching.

The third procedure used by PC to estimate monopoly profits is to attribute the price difference between brand name and private label items to monopoly profits. Monopoly profits are extracted by restricting the options available to consumers—not by providing consumers with a free choice between alternatives.

The purchase of a brand name item by a consumer is the result of a conscious decision to select the item from a shelf containing both the brand name and private label item. Moreover, the price of each item is marked on each container and/or the shelf. The rational consumer will purchase the brand name only if its price premium is less than the consumer's perceived difference in value (utility) between the two items. Because the consumer willingly pays the price difference to acquire what is perceived as a higher quality product, it hardly seems reasonable to call the price difference monopoly profits. Rather, the price difference is a lower bound estimate of the added quality (value) of the brand name item relative to the private label item. Arguments that there really is no technical difference between the two items are irrelevant. Quality—like beauty—is in the eye of the beholder. The continued existence of price premiums between brand name and private labels is strong evidence that for some consumers (those that buy the brand name item) the higher value (utility) justifies the price differential. Thus, it is erroneous to use the price differential as a measure of monopoly profits.

The PC recommendation for restructuring the U.S. food-processing industry was a foregone conclusion given the conceptual framework used for their analysis. Use of the alternative conceptual framework (i.e., demonstrating that the oligopolistic firms' costs are at level C_1 and not level C_2 while the production costs in an atomistic structure are at level C_a) would introduce more objectivity into their analysis. This framework leaves open the possibility that the authors will arrive at the same set of recommendations. However, this framework will require that PC be much more rigorous in their analysis and that they substantiate some of the unsupported value judgments contained in the current paper. If the revised analysis leads PC to the same conclusions they will then have much more convincing evidence that the U.S. food-processing industry should be restructured.

Estimates of Consumer Loss Due to Monopoly in the U.S. Food-Manufacturing Industries: Reply

Russell C. Parker and John M. Connor

We appreciate this opportunity to respond to these two comments. Our article presented three independent estimates of the loss calculated, using widely different data sets and methodological approaches. Two of the approaches used statistical models from standard works in industrial organization. The third was based on original work by the authors, using regression analysis to refine a set of brand-by-brand price and sales data uniquely available for the food industries.

Professors O'Rourke and Greig (OG) open their comment by arguing that the Parker-Connor (PC) conclusion that the food industries are imposing a social cost on consumers is highly misleading because we failed to recognize that the high and increasing profitability of food manufacturing actually represents declining "real" rates of return on assets and stockholders' equity of food-manufacturing industries. They allege that the "real" rates are below the opportunity costs of capital. Real rates of profit are defined as the actual rate of profits on total assets and on stockholders' equity relative to the prime rate of interest in the economy.

Since OG use total assets as the denominator in their rate of return, but exclude interest payment in the numerator, the values of their "real" rates of return are low. Interest payments should not be excluded because many companies borrow money, for which they pay interest, to finance part of their assets. The OG real rate of return on assets is peculiar because it is a function of the amount of borrowing as well as business success. Industrial organization studies either include interest in the numerator of the asset ratio or use profits as a percentage of stockholders' equity. The latter expresses profits such that it is easier to determine if stockholders are sufficiently rewarded to attract and maintain necessary ownership capital. It is noteworthy that the OG series of profits on equity shows essentially the same trend as that which PC reported, even after the OG deflation procedure is applied. The choice of 1975 as the terminal year did not affect the upward trend in food manufacturers' profits; any terminal year from 1970 to 1979 confirms the trend. Their ending period does not show as high a level for food manufacturers relative to all-manufacturing (table 1) as PC did, but this was primarily because of their final period capturing a relative boom in the cycle of all-manufacturing profits.

Contrary to the assertion made in the OG comment, the PC estimate of excess profits in no way depends on a fortuitous selection of the year 1975. Our estimate was based on the application of 1972 to 1975 industry structure data to a profit function fitted to data for a five-year period in the 1950s. This should also eliminate the OG concern about the effects of inflation on profits since inflation was low during the period over which the equation was fitted.

The claim that inflation causes reported rates of profitability to rise markedly above real rates is supported neither by recent empirical investigations nor, curiously, by their own citations. Fama has calculated inflation-adjusted rates of corporate profitability on assets for 1968–78. Incidentally, he also argues that the numerator should include net interest payments. The denominator should be real total capital, assets evaluated at replacement cost. Profits are adjusted downward for inflation-caused inventory profits and for underdepreciation caused by valuation of assets at historical costs. Cash flow for interest payments and depreciation has increased enormously over the 1950–78 period. Nevertheless, Fama's results indicate that average corporate profits in the 1970s were higher than those in the 1950s (8.1% versus 7.7%), though not so high as in the 1960s. Feldstein and Summers, using a similar method, also conclude that there is no evidence of a long-term fall in the rate of return to nonfinancial corporate capital, 1948–76. OG have made no such adjustments. Finally, the relevance of the Malkiel reference made by OG eludes us. Malkiel's only reference to profits is a passionate argument for corporate tax relief through depreciation-rules changes as a means of encouraging productivity.

The use of the prime interest rate as a measure of opportunity costs assumes that the value of a dollar of interest income and a dollar of after-tax accounting profit would be identical to an investor if risk were held constant. Such an assumption, however, ignores the income tax advantages with stock ownership, such as dividend exclusions and tax rates on capital gains, that are about half those applicable to interest income. It also ignores any effect that inflation has on increasing the current

The views expressed in this Reply do not necessarily represent those of their respective agencies.

market or replacement value of physical assets owned by companies. Financial assets, which bear interest payments, do not inflate but remain fixed in terms of dollars, which decline in purchasing power during inflation. It is possible during periods of rapid inflation for investors to consider zero or even negative company profits superior to high rates of monetary income earned in the form of interest. The real income of a recipient of interest could be negative if the inflation rate exceeded the interest rate. On the other hand, if the physical productivity of a company's assets remains the same, the real wealth of their owners should tend to stay constant during inflation.

A more appropriate extension of the analysis of company profit performance on invested capital than the one offered in the comment would be to look at relative changes in stock prices, disposals of companies below their book values, failure rates of technically efficient firms, the inability of such companies to float new stock issues or to borrow needed capital, and evidence of undercapitalization. Although the present authors have not made an exhaustive study, there appears to be little evidence that food companies are failing these market tests. We see no merit in departing, as OG have done, from these more traditional economic analyses.

Excess profits were only one of the components of the cost-components approach. Excess profits were about 30% of the total consumer loss. By failing to consider the inefficiency costs of monopolies as part of the overcharge, OG imply that consumers are irrationally obsessed with industry profits. In fact, consumers should be concerned primarily about how much higher prices are costing them and only secondarily with the level of profits that monopolists are receiving.

The data on profit trends were included in our review of industry structure merely to provide a motivation for our study—circumstantial evidence that a competitive problem may exist. It is entirely possible for a high consumer overcharge to exist in industries experiencing negative profits.

The assertion by OG that we somehow "overlooked" studies pointing to small monopoly losses (e.g., those by Schwartzman and Worcester) is irrelevant because those studies are estimates of the deadweight loss only. OG are confused over the distinction between consumer loss and net social loss—a distinction we belabored in our article.

The statistical flaws OG allege are primarily rehashes of limitations already made explicit with appropriate caveats by PC. Regarding the alleged flaw in the first of the estimates, which was an estimate derived by adding together the separate estimates of individual overcharge components, the commentors apparently misread the PC article. We described Scherer's estimates, as Scherer himself did, as "iffy" and "subjective." We used the Scherer textbook only as an acceptable source for describing the components of overcharge. We did not use Scherer's estimates in computing the major components of overcharge.

The two main components, which together constituted over 60% of our total overcharge estimate and were the major factors in estimating allocative inefficiency, were estimated from data and models specific to the food-manufacturing industries. Only a third of our total estimate was an extrapolation of Scherer's estimates. In describing these extrapolations, the present authors cautioned that they were the "least reliable of our estimates" and "included mainly for heuristic reasons." OG, in a misleading fashion, focus on these latter estimates in their discussion. Lest there be no mistake, we continue to question the reliability of these extrapolations both because of the data from which they were extrapolated and the method of extrapolation. However, considering the high values estimated for the two principal components of overcharge, there would seem to be little question that there should also be a significant amount of X-inefficiency. Had Scherer's percentage for the residual X-inefficiencies been applied directly, without the questionable adjustments for the relatively higher levels of food manufacturer concentration and advertising intensity, the extrapolated values would have totalled \$1.5 billion. This would have yielded a total overcharge estimate of 9.25 billion—not far from the \$10 billion which we reported as the likely low end of the error range.

Our second overcharge estimate was based on a regression analysis of census price-cost margin data. Our estimate held constant all factors, other than competitive structure factors. The OG charge that we "arbitrarily" chose CR-4 = 40% as our workable competitive standard is disturbing. In the body of the article (Parker and Connor 1979) we cite Scherer as an authority. But several other citations are included in PC (1978, p. 67), as well as a modest analysis of the level of CR-4 justified by estimates of minimum optimal scale. This evidence and subsequent searches of the literature on the "critical" concentration ratio leave us convinced that the CR-4 = 40% is a realistic dividing line for workable competition in most national market food-manufacturing industries. We did not calculate our estimates of consumer loss against the impossibly utopian standard of atomistic competition.

The presentation of the price-cost margin section began with a brief historical development. We gave the reader the initial Collins-Preston equation (1) and a refit based on 1970s' data (eq. 2). However, our analysis advanced beyond these historical equations. We fit a third equation, incorporating the more complete specification which benefitted from research during the last decade. Our article stated that "the authors believe that the estimate from equation (3) is superior" (p. 633). Despite this statement, OG choose to level their guns exclusively on the historical equations (1) and (2) and point out nothing more than what was stated, namely, that equations (1) and (2) show substantial

"variability in overcharge amounts due to the choice of the level of concentration defined as competitive" (p. 633).

Their only criticism of the preferred equation (3) is that the maximum price-cost margin point for an industry occurs at an advertising rate of 11% on sales. They ask why food manufacturers are not spending more on advertising since a higher rate would yield more monopoly profits. Besides their inexplicable confusion between monopoly overcharge, which was the object of the regression equation, and monopoly profits, which is only one component of overcharge, their criticism assumes that all products have a maximum potential for differentiation. In fact, products have varying degrees of limitations—the nature and importance of the product, grade labeling, alternative product availability, and a number of other factors. In our analysis, each observed point is assumed to be in equilibrium with advertising applied by each firm so as to maximize its rate of return. The appropriate question that should be asked of our equation is how well does it fit the data in the relevant range, not the meaning of some point far beyond that range. If our equation describes accurately in the relevant range, then the calculated overcharge amounts should be equally accurate. By their silence on this point, one must infer that OG are satisfied with this essential characteristic of equation (3).

The third estimate of overcharge was based on a regression analysis of the price differences between private labels and national brands of consumer food products. This approach involved not only a totally different kind of dependent variable than that used in the price-cost margin approach but also afforded a much more dissaggregated level of analysis. OG criticize our disaggregation on the grounds that the SIC product class (and industry) categories often are too narrow and do not represent well-defined markets. While it is true that SIC definitions were not designed specifically to meet the requirements of industrial organization research, virtually all such econometric studies have employed SIC-based data simply because they are the best available. If anything, the consensus is that SIC 4-digit and 5-digit categories tend to be overly broad definitions of true markets (Wilcox and Shepherd 1975, p. 43). Moreover, the OG illustration of the five dairy industries (butter, cheese, canned milk, ice cream, and fluid milk) as too narrowly defined is a good example of one of their "unsupported assertions." They imply that consumer substitution is high among the five industries, thereby introducing considerable interindustry competition. The most reliable U.S. Department of Agriculture estimates of cross elasticities of demand with respect to price fail to support their view; not one of the twenty possible cross elasticities among the five dairy industries exceeded the 0.10 level (Huang). The marketplace provides further evidence that SIC food product classes are not too narrow, as claimed. Most large food manufacturers purchase data from marketing services firms like Nielsen Company, which use classifications typically narrower but highly consistent with census product classes.

O'Rourke and Greig charge that the national brand-private label model is not based on any "tested, coherent theory." A closer reading by OG of the text on page 634, for a discussion of advertising effects and page 635, for the reference to an article by Nickell and Metcalf would have provided OG the theoretical basis for including the questionable variables. Nickell and Metcalf do a rather good job of laying out a theoretical basis for explaining national brand-private label price differences; they also test an original U.K. data set using a model very similar to PC.

As well as ad hocery, the OG comment alleges that PC ignore the problems of physical and psychic quality differences between private labels and national brands. In fact, we reported the findings of all such studies we could locate, including the one by Jafri and Lifferth offered in the comment as an example. The PC discussion raised several concerns and reservations concerning the general conclusion of these studies, namely, that no significant differences in quality exist between private labels and national brands. It should be noted that the existence of quality differences per se does not weaken the PC results, not even when those quality differences are associated with higher prices. The significance of the relationships could be challenged only if quality differences were positively associated with values of those independent variables which measure the aspects of structure used to estimate overcharge. If the quality differences of national brand products of high-concentration industries (such as puffed wheat cereal by Quaker vs. private label puffed wheat cereal) were generally greater than the quality differences in low-concentration industries, such as prepared meats, then there would be an upward bias in the overcharge estimate. Even if there were such an association, the bias introduced could still be insignificant.

OG believe that we unfairly single out advertising as a source of undesirable changes in the food system. They illustrate their point with a quotation (Parker and Connor, p. 629) that is taken out of context. That sentence listed plausible impacts that lay outside the scope of our research and about which we offered no judgement. Our policy suggestions on advertising are deduced from the coefficient values of our estimating equations (3) and (3.1), as well as other cited research. OG are correct that our model considers exogenous several factors (e.g., growth of the leisure industry) that may affect aggregate food demand. However, the present authors do not see how these factors would weaken the values of the advertising coefficients or their statistical significance.

OG's final point on the private label-national brand estimate is that national brand producers carry the cost of product innovation, while private labels only follow. Thus, they say, the price differ-

ence that is observed reflects a real social cost. Let us suppose that there is such an effect and that the variable measuring product growth, which was introduced to control for this effect, did not capture it. Are there data that might indicate the magnitude of the resulting bias? National Science Foundation data show that the food and kindred product industries rank lowest except for primary metals in terms of intensity of R&D activity. Worley found, in addition, that they were the only major group of industries where R&D intensity was inversely related to company size. These data do not suggest that the brands of large national companies carry a heavy burden of product development, and therefore suggest only a small potential bias if there was, indeed, a problem with equation specification. However, this may be a useful area for future research.

Bullock's main criticism is that it is theoretically possible for consumer welfare to be higher under monopoly than under pure competition if the average costs of production and distribution are lower in the monopoly case. Of course, we agree with Bullock's exposition of this possibility because we too are familiar with the textbook discussions of it, such as the initial pages (pp. 21–22) of Scherer's (1980) textbook. And we invite Bullock to look at figure 2.4 in Scherer, which is practically identical to his figure.

The resolution of this issue requires an empirical investigation to determine whether the largest firms have costs significantly lower than their smaller rivals (what he calls "atomistically sized firms"). We do not believe the answer is quite as simple as Bullock implied with his undocumented assertion that larger food firms have "replaced" smaller ones over the last twenty-five years, and that this change has occurred only because the larger firms were always more efficient. Bullock's simple survivor analysis blurs important distinctions such as technological versus pecuniary advantages of size, plant versus multiplant economies of scale, and specialized-firm versus conglomerate strategies (Scherer et al. 1975). Even a casual examination of basic census data on labor productivity differences among food-processing plants reveals that in most industries the most efficient size class lies between the extremes, suggesting the prevalence of the traditional U-shaped average cost curve. (Total factor productivity of food-manufacturing plants is not available by size classes.) Bullock's fascination with sheer size overlooks the fact that from a competitive point of view, the relevant consideration is optimal plant size relative to the market. Because national food-manufacturing markets are so large, it is unusual for a single plant (even the largest in the industry) to account for as much as 5% of the total shipments.

Both OG and Bullock cite a bulletin by Greig, which purports to estimate costs due to atomistic competition in the food-manufacturing industries. Greig's "method" reveals an inadequate understanding of the equilibrium assumptions underlying industrial organization theory. Workable competition is always assumed to be in long-run general equilibrium; firms are assumed to be producing at their minimum optimal scales. In the atomistic state apparently envisioned by Greig, firms are so miniscule that they are producing at levels below their technological optimum.

One might also fault Greig for his misuse of basic macroeconomic concepts, as well. In his adaptation of the Scherer estimates of consumer loss due to market power in the food industries, Greig takes 6.2% of shipments in SIC-20 instead of the appropriate measure of the "contribution to GNP," value added. This exercise led to an erroneously inflated estimate of consumer loss.

Bullock further asserts that the conceptual framework for our analysis guarantees that our estimates of consumer overcharge are large and positive. Adoption of the framework implied by his figure, he states, would introduce "more objectivity" and "rigor" into the analysis. This criticism is baseless. First, the only difference between Bullock's model and ours is the relative positions of the competitive price Pc and the monopoly price Pm. However, the two econometric models we used to estimate overcharges are perfectly capable of handling positive or negative margins or price differences. In fact, had Bullock examined our SAMI data source, he would have discovered that there were several cases where average private label prices exceeded average national brand prices. Second, for several industries, our models predicted no overcharge. In principle, all the industry estimates could have been zero.

In addition, Bullock questions the theoretical assumption of our national brand-private label price difference model that these differences contain information about overcharges. To Bullock, both price difference and quality difference considerations between national brands and private labels are irrelevant. The mere fact that consumers willingly pay the price differences means that consumers are maximizing utility and suffering no loss. If consumers perceive a quality difference, that is all that counts. Underlying this criticism is an abiding faith that markets never fail to be efficient. Needless to say, Bullock's faith ignores a huge body of microeconomic and industrial organization literature, declares a major area of academic curricula in American universities obsolete, and implies that the largest identified specialty in the American economics profession is irrelevant. Aside from these small matters, it also leaves several questions unanswered. In what sense do consumers make willing choices if high search costs are necessary and if markets are subject to large expenditures on persuasive advertising? In what sense is the supracompetitive equilibrium, that theory which predicts when there are high search costs, efficient? In a more practical vein, does it not do injury to serious economic analysis to assume that physically identical products that may simultaneously come

off of the same production lines, but are branded with highly advertised labels, give 30% or more additional satisfaction? Would it not be appropriate to question whether consumer choice is adequately informed?

The Darwinian-type faith, expressed in both comments, that any structure or behavior that emerges from markets necessarily maximizes efficiency leads their authors to label the PC research, which is not based on this faith, as prejudiced. The authors of the comments require that until PC can demonstrate evidence of specific instances of food-manufacturer management laxity and list specific management perquisites not justified by efficiency, there is no basis for a model which has *X*-inefficiency as a component of consumer loss. We reject this requirement as overburdensome in light of the economic literature of the effects of monopoly. We also reject the burden required of us, especially by Bullock, that we prove the superior performance of atomistically structured food-manufacturing industries. It is obvious from our assumption that any industry with less than 40% 4-firm concentration is competitive, that we employ a workable, not atomistic, structural standard.

The short PC policy section that inflames the authors of the comments was an attempt to make modest suggestions of some of the public policy implications of our research. In drafting our discussion, we tried to touch on only those options which, in our opinion, have played the most prominent role in congressional hearings and in the antitrust literature. We reject the criticism that we should have measured the costs and benefits of each policy option before mentioning it. Our policy section discussed the likely policy significance of the size of our consumer loss estimates and of some of the estimated parameters. This limited objective was, in our opinion, consistent with the limited scope of the paper as it appeared in this *Journal*.

Mitigating the Effects of Multicollinearity Using Exact and Stochastic Restrictions: The Case of an Aggregate Agricultural Production Function in Thailand: Comment

R. Carter Hill, Rod F. Ziemer, and Fred C. White

Mittelhammer, Young, Tasanasanta, and Connelly in estimating an aggregate agricultural production function use a variety of techniques to deal with multicollinearity present in their sample, including exact and stochastically restricted least squares and principal components regression.[1] They claim that consideration of these techniques allowed mitigation of a serious multicollinearity problem present in their data and permitted more precise parameter estimates. The authors also hold that two of the techniques they considered "generally outperformed OLS in terms of risk and overall reasonableness . . . (p. 199). While the empirical evidence Mittelhammer et al. present is convincing and the product of sound econometrics, we feel that some important limitations of the estimation techniques they employed as alternatives to ordinary least squares (OLS) were not sufficiently stressed. Furthermore, we will provide estimators that are unambiguously superior to least squares under a variety of standard loss functions.

Problems in Achieving Precise Estimation Using Restricted Least Squares and Some Alternatives

Combining sample observations with exact or stochastic restrictions has the effect of reducing estimator sampling variability relative to that of OLS. Even if the restrictions are incorrect (or biased in the case of stochastic restrictions), implying that the restricted least-squares (RLS) estimator is biased, the mean square error or risk of the RLS estimator may be less than that of OLS. Unfortunately, the potential risk gain occurs only over a relatively small portion of the parameter space where the restrictions are close to being correct (where the meaning of "close" depends on the risk function adopted). Furthermore, RLS estimators have risk functions that are unbounded in the sense that the further the restrictions are from being true, the greater the risk of the estimator. Thus, while it is true that RLS estimators have smaller risk than OLS under appropriate conditions, those conditions depend upon the true parameter values, which are unknown. Consequently, when using exact or stochastic restrictions, the researcher never knows whether a risk improvement over OLS under standard loss functions is realized.

Because the true parameter values are unknown, a common practice is to test statistically whether RLS is preferred to OLS under one of the standard risk functions described by Mittelhammer et al. and use the RLS estimator only if it is not rejected as being better then OLS on the basis of a hypothesis test. However, as suggested by Mittelhammer et al., such a pretest estimator has lower risk than OLS only over a finite portion of the parameter space that depends, among other things, on the true parameter values and the significance level of the test (Judge and Bock; Judge, Bock, Yancy; Wallace). Furthermore, Sclove, Morris, and Radhakrishnan have shown that the traditional pretest estimator is inadmissible; that is, another estimator exists that has risk at least as small regardless of the true parameter values. Perhaps even more disheartening is that the sampling distribution of the pretest estimators is unknown, thus preventing usual tests of hypotheses and confidence interval statements.

While there is little positive that can be said about the hypothesis-testing dilemma, additional progress can be made with respect to obtaining point estimates that are superior to OLS under a general risk function of the form,

$$R(\hat{\beta},\beta) = \frac{E(\hat{\beta} - \beta)'Q(\hat{\beta} - \beta)}{\sigma^2}, \tag{1}$$

where $\hat{\beta}$ is an estimator of the parameter vector β, σ^2 is the error term variance defined below, and Q is a positive definite and symmetric matrix. Two common choices of Q are an identity matrix, yielding the weak mean square error criterion, and $Q = X'X$, yielding the mean square error of prediction criterion.

Let the linear model of concern be

$$\mathbf{y} = X\beta + \mathbf{e}, \tag{2}$$

where $\mathbf{y}$ is a $(T \times 1)$ vector of endogenous variable values, X is a $(T \times k)$ matrix of regressor values, β is a $(k \times 1)$ parameter vector and $\mathbf{e}$ is a $(T \times 1)$ vector of error terms normally distributed with mean zero and common variance, σ^2. The OLS estimator of β is $\mathbf{b} = (X'X)^{-1}X'\mathbf{y}$ which is indepen-

The authors are, respectively, associate professor, Department of Economics, and graduate research assistant and professor Department of Agricultural Economics, University of Georgia.

[1] Principal components regression can be shown to be equivalent to a restricted least squares estimator (Fomby and Hill).

dent of $s = \mathbf{y}'M\mathbf{y} \sim \sigma^2\chi^2_{(T-k)}$, where $M = I - X(X'X)^{-1}X'$. Let the linear equations $R\beta = \mathbf{r}$ define J linearly independent, exact restrictions on β. The RLS estimator for β can then be written:

$$(3)\quad \mathbf{b}^* = \mathbf{b} + (X'X)^{-1}R'[R(X'X)^{-1}R']^{-1}(\mathbf{r} - R\mathbf{b}),$$

while the general Stein-like estimator can be written

$$(4)\quad \delta(\mathbf{b}, s) = \left[1 - \frac{as}{(\mathbf{r} - R\mathbf{b})'[R(X'X)^{-1}R']^{-1}(\mathbf{r} - R\mathbf{b})}\right] \times (\mathbf{b} - \mathbf{b}^*) - \mathbf{b}^*,$$

which is minimax and dominates the OLS estimator[2] if $k \geq 3$ and

$$(5)\quad 0 \leq a \leq 2\left(\lambda_k \sum_{i=1}^{k} \frac{1}{\lambda_i} - 2\right)\Big/(T - k + 2),$$

if $Q = I$ and

$$(6)\quad 0 \leq a \leq 2(k - 2)/(T - k + 2),$$

if $Q = X'X$. Here λ_i is the ith largest characteristic root of $X'X$, λ_k being the smallest. Note that if $Q = X'X$, or that the mean square error of prediction loss function is chosen, the value of the shrinkage factor, a, is not affected by λ_k or the degree of multicollinearity. The estimator described in (4) is in turn dominated by its positive-part variant

$$(7)\quad \delta^+(\mathbf{b}, s) = \left[1 - \frac{as}{(\mathbf{r} - R\mathbf{b})'[R(X'X)^{-1}R']^{-1}(\mathbf{r} - R\mathbf{b})}\right] I_{[a,\infty)}\left[\frac{(\mathbf{r} - R\mathbf{b})'[R(X'X)^{-1}R']^{-1}(\mathbf{r} - R\mathbf{b})}{s}\right] \times (\mathbf{b} - \mathbf{b}^*) + \mathbf{b}^*,$$

where $I_{[\cdot)}(c)$ is an indicator function that is equal to one if c falls within the stated interval, $[\cdot)$, but zero otherwise. Note that $(\mathbf{r} - R\mathbf{b})'[R(X'X)^{-1}R']^{-1}(\mathbf{r} - R\mathbf{b})/s$ is equal to $J \cdot F_{(J,T-k)}/(T - k)$, where $F_{(J,T-k)}$ is the F-statistic as reported by Mittelhammer et al. If $Q = X'X$ is chosen, then $a = (k - 2)/(T - k + 2) = .286$ for the Mittelhammer et al. models. The positive-part Stein-like estimator described in (7) that combines their reported OLS and principal components estimates can then be written,

$$(8)\quad \delta^+(\mathbf{b}, s) = \left[1 - \frac{.286}{.401}\right](\mathbf{b} - \mathbf{b}^*) - \mathbf{b}^*.$$

Results of applying the rule described in (8) along with the OLS and RLS (principal components regression) results of Mittelhammer et al. are presented in table 1.[3] As is apparent from table 1, the Stein-rule estimator shrinks the OLS estimates toward the prior information, the principal components estimates in this case.

The Stein-like estimators described in (4) and (7) provide point estimates that are superior to least squares under common loss functions regardless of the true parameter values and thus regardless of whether the exact restrictions are true or not. Unlike the traditional pretest estimator, these estimators do not choose between the OLS and RLS estimates, but rather, loosely speaking, average these estimates depending on the value of the appropriate F-statistic. The larger the value of F, holding T and k constant, the less weight is given the RLS estimator. Major limitations of the Stein-like estimators are that they are nonlinear and have unknown sampling distributions, just like the pretest estimators. Furthermore, like the pretest estimators, the covariance matrix of a Stein-like estimator can be derived, but is quite complicated and dependent on the unknown parameter vector—thus is of little practical use. Despite these limitations however, the Stein-rules presented above provide a way to combine sample and nonsample information in a way that guarantees risk improvement over OLS.

Conclusions

In this note, two estimators are presented that provide point estimates superior to OLS. With regard to mitigating the effects of multicollinearity, these estimators provide more precise parameter estimates than least squares in the sense of having lower risk. More important, unlike conventional pretest procedures, these risk gains are guaranteed. It is still true, however, that the better the prior

Table 1. Production Function Results for Using Alternative Estimation Techniques

	Coefficients		
Variable	OLS	RLS	Stein-like
ln$A$	−4.5108	−.0045	−1.2978
ln$L$	.4937	.3436	.3867
ln$N$	3.2300	.4808	1.2698
ln$K$	.1668	.2017	.1917
t	−.0553	.0111	−.0080
D_1t	−.0036	0.0000	−.0010
D_2t	−.0022	0.0000	−.0006
D_3t	.0018	0.0000	.0003

Note: OLS and RLS are the results reported in Mittelhammer et al. for "Model 1" and "Model 5," respectively (p. 202).

[2] See Strawderman for a discussion of a generalized ridge-type estimator which also dominates least squares.

[3] For the results reported in "Model 2" (Mittelhammer et al., p. 202), the argument for the indicator function in equation (7) lies outside the interval $[a,\infty)$ for $Q = X'X$. Therefore the positive-part Stein-rule estimates are equivalent to the RLS estimates reported by the authors.

information, i.e., the exact restrictions, the greater the gain that is realized over least squares.[4]

Mitigating the Effects of Multicollinearity Using Exact and Stochastic Restrictions: The Case of an Aggregate Agricultural Production Function in Thailand: Reply

Ron C. Mittelhammer and Douglas L. Young

We thank Hill, Ziemer, and White (HZW) for their interest in our problem of mitigating the effects of severe multicollinearity and for their suggestion of a Stein-like estimator as an alternative estimator to those we examined. While the estimators HZW suggest can have attractive statistical properties under rather general conditions, we are less willing than they to discard the more conventional estimators, both for our specific problem and for many general applications. We will endeavor to support our reservations with technical arguments as well as on philosophical grounds.

We begin by noting that HZW have incorrectly stated the interval for the shrinkage factor 'a' in their Stein-like estimators (4) and (7) over which the estimator is known to dominate the OLS estimator [see their (5) and (6)]. It can be shown[1] that when using the risk function,

$$(1) \qquad R(\hat{\beta},\beta) = \frac{E(\hat{\beta} - \beta)'Q(\hat{\beta} - \beta)}{\sigma^2}.$$

The Stein-like estimators of Hill et al. are minimax and dominate the OLS estimator if

$$(2) \quad 0 \leq a \leq 2\left[\frac{tr(R(X'X)^{-1}R')^{-1}\, R(X'X)^{-2}R'}{\zeta_l} - 2\right] \Big/ (T - K + 2),$$

for $Q = I$, and

$$(3) \qquad 0 \leq a \leq 2(J - 2)/(T - K + 2),$$

for $Q = X'X$, where ζ_l is the largest characteristic root of $[R(X'X)^{-1}R']^{-1}\, R(X'X)^{-2}R'$, J is the number of independent linear constraints on the parameters of the linear model, and other notation is consistent with that used in HZW. It is recognized from (2) or (3) that there will exist a nonzero choice of 'a' only when the researcher has utilized a restricted least squares estimator in defining the Stein-like estimator that incorporates three or more independent constraints on the parameters, i.e., $J \geq 3$. Thus, for example, if a researcher were utilizing principal components regression in which only two components were deleted, corresponding to two constraints on the parameters of the linear model, the use of the Stein-like estimator of HZW to shrink the OLS estimator towards the principal components estimator would not be desirable under squared error risk ($Q = I$) or predictive risk ($Q = X'X$). In the special case where $J = K$, so that the restricted least squares estimator, b^*, used in the Stein-like estimator is defined as the nonstochastic $K \times 1$ vector $\mathbf{R}^{-1}r$, the Hill, Ziemer, and White bounds are correct. Of course, in the context of usual applications of principal components regression where the dependent variable is regressed on principal components as explanatory variables, components are deleted, and then estimates of parameters in the original coordinate space are generated, the special case where $J = K$ is of virtually no interest, because this is tantamount to restricting all parameters in the original coordinate space to zero. Thus, the applied researcher should be aware of the general bounds (2) and (3) should he or she be interested in applying one of the Stein-like estimators suggested by HZW to a given estimation problem.

At this point, it becomes interesting to ascertain whether the Stein-like estimators suggested by HZW can be defined so as to dominate the OLS estimator and provide improved parameter estimates. We should note that one of our original problem objectives was to obtain precise estimates of the parameters of the agricultural production function we had specified. And, to be sure, the squared error risk function, i.e., (1) with $Q = I$, is useful in gauging estimation performance in the parameter space. Because in our case $J = 6 \geq 3$, calculation of the estimator could be useful. Unfortunately, our case is an example where the Stein-like estimator is not unambiguously superior to the OLS estimator, for when the interval for 'a' suggested by (2) is calculated, we find the calculated upper bound for 'a' to be $-.0935$. Thus, the Stein-like estimators suggested by HZW do not possess the property of dominating the OLS estimators in our case, and thus, their principal virtue is not realized. It should be noted that the failure of the Stein-like estimator in our case was due to a mul-

Ron C. Mittelhammer and Douglas L. Young are assistant agricultural economists and assistant professors in the Department of Agricultural Economics at Washington State University.

[1] The proof of this result, as well as others included in this paper, are omitted due to space limitations. The proofs are essentially variations on proofs contained in Judge and Bock in their discussion of Stein-like estimators. Interested readers may obtain these proofs upon request from Ron Mittelhammer.

ticollinearity structure in the matrix $[R(X'X)^{-1}R']^{-1} R(X'X)^{-2}R'$ that resulted in ζ_l being quite large relative to the remaining smaller characteristic roots. Whether this failure occurs in general depends on the structure on the multicollinearity in any given problem. The failure is less likely to occur when $[R(X'X)^{-1} R(X'X)^{-2}R'$ has two or more large characteristic roots of roughly similar magnitude.

Although the estimators suggested by HZW were not useful for improving the estimates of the parameters of the production function themselves, as judged by the squared-error risk criterion, they are superior to the OLS estimator if judged by the predictive risk criterion, i.e., (1) with $Q = X'X$, as HZW contend. That is, in our problem with $J = 6$, there do exist choices of the shrinkage factor 'a' that, when used in the Stein-like estimators suggested by HZW, produce an estimator which dominates the OLS estimator and is minimax under the predictive risk measure. Because an objective of our original problem was to obtain precise predictions of agricultural output, consideration of predictive performance was relevant.

We should point out that using the midpoint of the interval for 'a'—recall (3)—in our case where $J = 6$, $T = 27$, and $K = 8$, results in a choice of the shrinkage factor equal to .190, and not .286, as utilized by HZW. The choice of the midpoint of the interval has special significance when the general Stein-like estimator is used—see HZW, equation (4), for it represents the choice of the shrinkage factor that results in the Stein-like estimator with smallest predictive risk, regardless of the degree of error in the restrictions imposed. However, unlike the general Stein-like estimator, the positive-part estimator—see HZW, equation (7)—is such that there does not exist a choice of 'a' in the interval (3), which is optimal from the predictive risk standpoint, because the risk functions of the positive part estimators can cross for various choices of 'a'. Nonetheless, it is known that the positive part estimator dominates the general Stein-like estimator in predictive risk for corresponding choices of 'a'. Using the midpoint value of 'a' = .190, we calculate the general Stein-like or positive part estimates (they are numerically identical in this case) for our production function to be

$$(4)\quad y = .0930\, L^{.4225}\, N^{1.9274}\, K^{.1833} \exp\{-.0238_t - .0020D_1t - .0012D_2t + .0009D_3t\},$$

which are in contrast to the estimates presented by HZW.[2]

Now that the Stein-like estimates of the parameters, which dominate OLS estimates in predictive risk, have been defined, the question is whether they should be utilized for prediction or the restricted least squares estimates should be used.[3] What are the most important benefits and costs of using the Stein-like estimator as opposed to using the restricted least squares estimator? The obvious advantage of the Stein-like estimator is that it is known to dominate the OLS estimator in predictive risk regardless of the validity of the constraints—how much better the Stein-like estimator is relative to the OLS estimator of course depends on how close the constraints are to being true (as measured by the size of the noncentrality parameter associated with the F-test of constraint validity). However, there is a potential cost to be paid for obtaining this guaranteed dominance. The Stein-like estimators do not dominate the restricted least squares estimator in predictive risk (nor in squared error risk). There is a subset of the parameter space where the constraints are nearly correct (small noncentrality parameter) and where the restricted least squares estimator can beat the Stein rule estimators in risk measure quite handily. For example, in a case such as ours with $J = 6$, $T = 27$, and $K = 8$, if the constraints imposed were actually correct, the general Stein-like estimator would have over twice the risk of the restricted least squares estimator.[4] A graphical illustration of these relationships is presented in figure 1 comparing OLS, restricted least squares (RLS), and the general Stein-like estimator when the shrinkage factor in the Stein-like estimator is chosen to be $(J - 2)/(T - K + 2)$, the midpoint of the interval in (3).

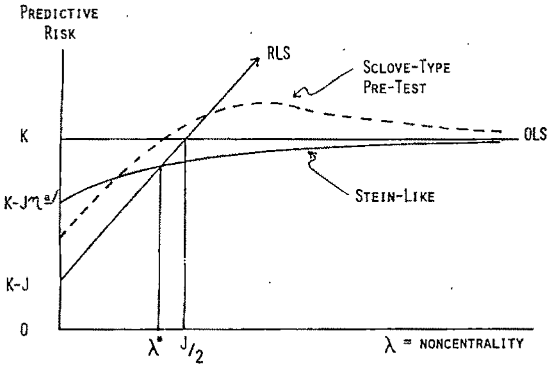
In application, the researcher never will know with certainty whether the restricted least squares or Stein-like estimator is superior with respect to predictive risk (or squared error risk). If the researcher is completely ignorant of the validity of his constraints, we must agree with HZW that Stein-like estimators, when they provide minimax alternatives to OLS, are attractive in terms of risk properties. In our case, although we feel there is a priori evidence to support zero restrictions on the dummy variables representing differential technological progress over government planning periods, we have little basis for presuming the validity of the zero restrictions on linear combinations of the parameters imposed by the deletion of three principal components. Faced with this ignorance, one might have suspected that we would find the suggestion of

---

[2] We note in passing that neither the Stein-like parameter estimates computed by HZW nor those reported in (4) appear to be theoretically plausible. Both labor elasticity estimates indicate well in excess of a 1% increase in output for a 1% increase in labor input, which strikes us as exhorbitant for the relatively aborabundant, low-wage Thai agricultural economy. The returns to scale estimates, 1.8482 in HZW and 2.5332 in (4), also greatly exceed theoretical expectations and empirical estimates generally found in the aggregate production function literature. Both Stein-like technology coefficient estimates are negative, implying technological decay in Thai agriculture between 1950 and 1976

[3] Following the terminology of HZW, when we refer in this reply to the restricted least squares estimator of the aggregate agricultural production function in our previous work, we are referring to the restricted least squares estimator represented by our principal components regression estimator (model 5 in table 2, Mittelhammer et al., p. 202).

[4] The actual predictive risk for the restricted least squares estimator is 2, and for the general Stein-like estimator, 4.381, in a case such as the one described, with the noncentrality parameter being zero (the constraints are correct).



[a] $\eta = \dfrac{(J-2)(T-K)}{J(T-K+2)}$, λ^* is that value of λ such that

$$\lambda = J/2 - E(1/\chi^2_{J,\lambda})\frac{(J-2)^2(T-K)}{2(T-K+2)}.$$

Figure 1. General predictive risk comparisons between OLS, RLS, optimal general Stein-like, and Sclove-type pretest estimators

the Stein-like estimators appealing. However, we were left with an uneasy feeling that we might be foregoing an opportunity for lowering predictive risk by choosing the Stein-like estimator as opposed to the restricted least squares estimator in this case. For example, with reference to figure 1, we find that in our problem the general Stein-like estimator's risk function crosses the risk function of the restricted least squares estimator when the noncentrality parameter equals $2.64 = \lambda^*$. The calculated F-value corresponding to the six restrictions imposed on the parameters of our production function specification was 1.27 (see Mittelhammer et al., p. 202, table 2). With reference to the noncentral F density with 6 and 19 degrees of freedom, and noncentrality parameter $\lambda = 2.64$, we find that $P[F_{6,19}; \lambda = 2.64 \geq 1.27] = .703$. Thus, there is very strong sample evidence supporting the hypothesis that $\lambda \leq 2.64$ and that the restricted least squares estimator is superior to the general Stein-like estimator in predictive risk. However, it is admittedly sample evidence of superiority and not an unequivocal guarantee. Furthermore, if we were to base our choice of estimator on a noncentral F-test of predictive risk superiority, a pretest estimator would be defined of the Sclove, Morris, Radhakrishvan form (see Judge and Bock, p. 189). An illustrative graph of a typical predictive risk function for the Sclove-type pretest estimator is included in figure 1. The pretest estimator would choose the restricted least squares estimator in our case for all critical levels of the risk superiority test associated with probabilities of type I error $\leq .703$. While the pretest estimator has the advantage of a bounded risk function (the restricted least squares estimator has unbounded risk), it is seen in figure 1 that the potential for gains over the Stein-like estimator is eroded. The exact position of the risk function depends on the choice of critical point for the superiority test where, roughly speaking, higher critical values pull the risk function of the pretest estimator towards the restricted least squares risk function (see Judge and Bock, chap. 3).

In light of the preceding discussion, it might appear prudent to accept the Stein-like estimates (4) as formidable competitors to the restricted least squares estimates for prediction purposes. In the absence of any further information on the location of the noncentrality parameter, the researcher might be wise to choose conservative estimates generated by the Stein-like estimators suggested by HZW. However, two final observations on the behavior of the Stein-like estimator motivate us to discard the Stein-like estimates and retain our restricted least squares estimates for use in deriving policy conclusions in our original research. First, we were alerted to the necessity of subjecting the Stein-like estimator to further scrutiny by the blatantly unrealistic decomposition of agricultural growth between conventional inputs and technological advance implied by the Stein-like estimates. Specifically, with reference to our original table 4 (Mittelhammer et al., p. 208), the conventional input share of increased agricultural output using the Stein-like estimates is calculated to be 238.4%, while the share due to technological progress equals −138.4%. Searching out an explanation for these rather startling results derived from estimates with supposedly attractive predictive risk properties, we found an answer in the definition of the predictive risk function itself. The Stein-like estimator is known to dominate the OLS estimator in predictive risk measure, where the predictive risk measure (1) with $Q = X'X$ is measuring expected squared distance between $\hat{\beta}$ and β in the $X'X$ metric, or equivalently, expected squared Euclidean distance between the vectors $\hat{y}$ and $E(y|X)$. As such, the predictive risk measure is relevant to predictions made conditional on the historically observed X matrix. The measure is a useful one and was of direct relevance in our case since output predictions for years included in the data set were required for the decomposition of agricultural growth. However, the decomposition calculation also required a prediction using 1976 levels of conventional inputs together with 1950 levels of the technology proxy variables, a set of values for the explanatory variables which was not in the data set X and is a situation quite removed from historical precedent.

We defined a risk measure of the form (1), where $Q = X_*'X_*$ and X_* was the $(n+1) \times K$ matrix comprised of the original X matrix with an additional row representing the appropriate explanatory variable values for this historically unprecedented situation. Thus, the new predictive risk function also measures the performance of the prediction of the expected value of agricultural production conditional on 1976 levels of conventional inputs and a 1950 level of the technology proxy. The bounds for the shrinkage factor utilized in the Stein-like estimator in this special case can be shown to equal

(5) $0 \leq a \leq 2\left[\frac{J - 2 + \eta}{1 + \eta} - 2\right] \Big/ (T - K + 2)$,

where $\eta = x_{n+1}\ S^{-1}R'(RS^{-1}R')^{-1}\ RS^{-1}\ X'_{n+1}$ and X_{n+1} is the row of explanatory variable values added to the X-matrix. The calculated upper bound in our problem was found to equal $-.0944$, and thus the Stein-like estimator is not useful for the prediction purposes of our study.

In concluding, we contend that the researcher plagued by severe multicollinearity is unlikely to find comfort by mechanically appealing to a single estimator whose principal virtue is dominance over OLS in some sense, be it the Stein-like estimator or some competitor. We believe our arguments above underscore the need to exercise sound case-by-case judgment in selecting estimators. Such judgment should include the definition of risk functions appropriate to the intended application of the results. It should also include an honest assessment of the reliability of any imposed constraints.

[Received January 1981.]

An Economic Evaluation of Alternative Peanut Policies: Delayed Reply

W. L. Nieuwoudt

In his "Comment," Trapp concludes that the year 1973 on which the peanut model of Nieuwoudt, Bullock, and Mathia (1976b) is based (hereafter called NBM) is atypical for the peanut market because high oilseed prices (soybeans and cotton) during 1973/74 shifted the peanut demand to the right for that year. More specifically, he concludes that where the NBM model predicts an increase in peanut production and gross revenue if the peanut program were abolished, the opposite will happen under more typical conditions. As evidence, he showed that production costs of peanuts exceeded estimated open market prices during 1970–76 except for 1973/74. Trapp's comment raises several questions which will be examined. It will be shown that his theoretical argument ignores a supply shift, and that his cost data include substantial rents.

Interrelationship between Supply and Demand Shifts

The main shifters in Trapp's peanut demand models are soybean and cottonseed prices. According to soil maps and opinions of peanut experts, about 1.4 million acres currently under soybeans (Southeast) and about .6 million acres under cotton (Southeast and Southwest) are suitable for peanut production (Nieuwoudt et al. 1976a). Peanuts and soybeans have similar agronomic characteristics; for example, rotation with other crops such as corn (Southeast) is recommended by the Extension Service in the interest of weed control. Fleming and White (1975) estimated regional supply functions for peanuts showing that gross income from soybeans and cotton are important shifters of peanut supply. A depressed oilseed market is thus expected not only to shift the peanut demand to the left, as illustrated by Trapp (figure 2), but should shift the peanut supply to the right. Theoretically the supply shift could be greater, smaller, or equal to the demand shift. A supply shift which offsets the demand shift would keep the ordering of *Pm*, *Pe*, and *Po* unchanged (Trapp, p. 109) leaving the conclusions drawn in the NBM study unaltered. Trapp's theoretical discussion creates a one-sided view by only focusing on a demand shift while ignoring a possible corresponding supply shift.

W. L. Nieuwoudt is an associate professor in the Department of Agricultural Economics at the University of Natal, Pietermaritzburg, South Africa.

Trapp quotes cost and marketing data to support his theoretical analysis. The data he used will be examined in relation to the NMB study.

Opportunity Cost of Peanuts

Trapp included land charges in his costs of production (U.S. Department of Agriculture ESCS budgets) to allow for opportunity income of other crops. The question is whether the data that he used, correctly reflect opportunity income of peanut production. According to him, his land charges figures "are largely exclusive of the effects of peanut allotment rentals upon land price since peanut acreage constitutes a small percentage of the land used in these areas." Evidence will be shown that contradicts this statement implying that peanut allotment rentals are a significant component of peanut cost of production quoted by Trapp. According to the USDA report (USDA ESCS *Report*, 15 June 1979), "cropland values for 1977 by crop-reporting districts were weighted by crop acreages in these districts to arrive at a separate land value for each crop for each State" (p. 3). Peanuts are grown in the United States in certain well-defined localities. In these specific areas, peanuts are one of the most important crops. Calculating land rents (land costs) using such a weighting procedure implies that the land cost figure determined for peanuts would include peanut allotment rents to an important extent. The USDA-ESCS report states further that composite land costs "include the value of land as well as the value placed on the peanut allotment" (p. 34), and that cost as measured for individual commodities is a derived total. In this context, income per acre equals costs per acre because all rents are accounted for (Euler theorem). A fall in oilseed prices as Trapp describes would have tended to increase peanut allotment rents as reflected in peanut budgets because of past peanut support prices, while opportunity costs of growing peanuts would have fallen. The sum total of land and allotment rents would not have changed.

To gain an impression of these opportunity costs, land costs for the main crops grown in peanut areas as reported in USDA-ESCS budgets are summarized in table 1. The data are revealing. Land cost figures included in USDA-ESCS peanut budgets are substantially higher than land cost included in budgets for substitute crops in the same

areas. For example, while land costs per acre in budgets for the main peanut substitutes in the Southeast for 1978 varied from $43 to $49, cost of land in peanut budgets were, respectively, $140 and $121 for the Georgia and North Carolina areas. This confirms the above conclusion that peanut land costs in peanut budgets (USDA-ESCS budgets, 1974–79) include substantial allotment rents. A better estimate of the opportunity costs of peanuts, for example in the Southeast, would be land costs (rents) of soybeans, corn, and to a lesser extent cotton and wheat.

If open market prices of peanuts exceed peanut costs in a given area, then if allotments are terminated, some allotment rents will be captured as land rents, and rent of peanut land (excluding allotment) should increase above current opportunity costs. This situation is depicted in Nieuwoudt's and Bullock's studies for all peanut areas except the nonirrigated peanuts in Texas. If Trapp's alternative conclusions are valid, however, then peanut land rents would fall to below current opportunity costs (Bullock, case 2). To investigate whether free market prices exceed peanut costs as Trapp has done, it thus appears reasonable to estimate peanut opportunity costs by prevailing rents of land of substitute crops as in table 1.

Allotment Transfers

Trapp (p. 108) states that in the NBM model, constant marginal cost of production is assumed while in actuality, the market for peanut allotments is less than perfectly competitive because peanut allotments can be transferred only within county borders. On the contrary, because data for fifty-nine resource areas were built into the NBM model, the phenomenon that peanut transfers are only permitted within county borders was one of the important checks on the validity of the NBM model (table 4), because allotment rents for counties could be compared with shadow prices on the model allotment constraints. The marginal cost curve for peanut production generated within the NBM model is positive sloping because individual resource areas included in this model have different comparative advantages, as is evident from differences in allotment rents. The long-run equilibrium price (free market) is only equal to the local average cost of production in a given county as generated within the model in the sense that the portion of peanut allotment rent transferred to land for the given county, in the form of a shadow price on land, is included in cost of production.

Trapp compared national cost data, determined as a weighted average of costs of production in current production areas, with open market peanut prices. In a free market, production would flow to lower cost areas, and production costs would fall. This phenomenon was incorporated in the NBM model. National cost data may overstate free market costs of production to a significant extent. Using cash rent data published in the USDA-ESCS reports and opportunity costs as measured in table 1, it is estimated that peanut prices (1977) need to fall by 5.4 cents per pound before peanuts would disappear from Georgia while in Texas it needs to fall .5 cents per pound. The NBM study estimated that peanut prices (1973) need to fall by 6.2 cents in Georgia, 1.30 cents in Texas dryland, and 3.9 cents for Texas irrigation before peanut production would disappear, which shows important differences in regional cost (opportunity cost inclusive).

Fall in Gross Revenue

Trapp concludes that where the NBM study showed an increase in gross revenue received from peanut sales, under more typical conditions it would decline. His argument creates the impression that producers according to the NBM model would be better off under a free market situation, while his study points to the opposite. This is not the case, as the NBM study estimates on pp. 490 and 492 (table 7) that producer surplus of all crops under free

Table 1. Costs Allocated to Land of Crops Grown in Peanut Areas

	Southeast ($ per acre)						Southwest ($ per acre)		Opportunity Cost (¢/lb.)	
	Peanuts									
Year	NC/VA	Georgia, Alabama	Soybeans	Corn	Cotton	Wheat	Peanuts	Grain Sorghum	Southeast	Southwest
1979			49.4	52.5	45.5	46.7		30.5	1.65	1.76
1978	121.2	140.2	46.2	49.1	42.6	43.7	43.3	28.6	1.56	1.82
1977	113.9	122.5	43.0	44.1	35.6	38.9	48.3	26.7	1.53	1.73
1976	100.3	83.5	41.3	45.8	41.3	41.6	39.4	25.5	1.58	1.56
1975	79.7	88.6	38.3	41.1	38.3	43.2	40.4	30.9	1.37	1.91
1974	93.8	70.4	36.9	41.3	36.6	NA	NA	30.8	1.37	1.96

Note: Based on estimated current value of cropland multiplied by current interest rates on Federal Land Bank mortgage loans. Data not available for 1970–1973. All data obtained from USDA ESCS budgets for subsequent years.

market conditions would be lower than under the current program.

If dollar sales from peanuts are actually lower under a free market situation, as Trapp concludes, then producer surplus also would be lower, which is in accordance with the NBM study although the magnitude of change would have been more. This clearly does not contradict the findings of the NBM study seen in the spirit in which policy objectives were evaluated. The NBM study states on p. 489, "No claim for the precision of these estimates is made. However, the consistent estimation procedures used across policy alternatives should provide a good measure of the relative impact each alternative has in the various dimensions."

Peanut sales and producer surplus for peanuts only were numbers reported in a table in the NBM study (p. 490), but it was never mentioned in the text as it was considered unimportant in relation to the theme of the paper. The objective of the paper was the evaluation of policies using criteria such as producer surplus (all crops), treasury loss, social costs, etc. The reason producer surplus of all crops fell in the NBM study while peanut sales expanded in the free market alternative is attributed to the loss in producer surplus of products displaced as captured in a programming model. If export prices exceed peanut costs (opportunity cost inclusive), peanut sales may in fact be more under a free market situation. This hypothesis cannot be tested using time-series data because time-series peanut supply functions cannot be estimated.

While a fall in peanut sales would still fall within the spectrum of conclusions arrived at in the NBM study, a reduction in peanut acreage (Trapp's other point) would seriously contradict estimates of the NBM study. The latter point will be further examined.

Free Market Prices for Peanuts

Trapp estimated "open" market prices for U.S. peanuts from local demand functions for edible and crushing peanuts as reported by Song; Song, Franzmann, Mead; Fleming and White (1975, 1976). The Song model is based on the period 1952–1972 and the Fleming model on the period 1960–1973. These models ignored the export market. Exports increased significantly during 1970–1979 and exceeded crushings for oil since about 1973, except for 1975 and 1976 when "toll" crushing occurred. The dramatic increase in peanut export prices during 1970–79 could also not be foreseen by the Song and Fleming models. Export prices of U.S. Runner peanuts increased threefold from 1970 to 1979.

There is also a mathematical problem in the way the Song and Fleming models were employed because Trapp's open market prices are below crushing prices. If the open market price is derived from crushing and edible demand functions, then the open market price determined in such a way must lie between the actual crushing and edible peanut prices of corresponding years if available supplies on the local market for those years are taken as given. Trapp reported "estimates of open market clearing prices for actual peanut production levels . . . ."

Only the larger peanut kernels are suitable for export as edible peanuts, and it does appear reasonable that the net export price would have been close to the crushing price and slightly better during the period, because if the crushing price is higher more peanuts would be crushed. The U.S. share in the world peanut market is about 18% (Fleming and White 1976), and world peanut prices should be a good indication of U.S. free market prices. It can thus be concluded that U.S. free market prices for the period 1970–1979 would have been close to actual crushing prices. Trapp's estimates of free market prices were generally well below actual crushing prices; for example, the actual crushing price in 1973 was 12¢ per pound, but the free market price was estimated at 9.88¢ per pound.

To test Trapp's statement that free market peanut production would decline, new data need to be presented on export prices and costs, which fall outside the scope of this Reply. According to The Overseas Farmers Co-operative (London), export prices of U.S. Runner peanuts increased from 9.1¢ per pound in 1970 to 27.1¢ per pound in 1979. If USDA ESCS cost data are adjusted using opportunity cost data as presented in table 1, it appears possible that U.S. peanut production may have expanded under free market conditions for most of the years during the period 1970–79, contrary to Trapp's conclusion.

The main criticisms of Trapp's study are that although he used official USDA budgets, allotment rents are reflected in peanut costs while the export market was also ignored, although exports exceeded crushing since 1973 except for 1975 and 1976 when "toll" crushing occurred.

Reconciling Agricultural Pricing, Environmental, Conservation, Energy, and Structural Concerns

Marshall A. Martin

After two decades of relatively stable prices, stagnant export growth, and relatively cheap energy, U.S. agriculture underwent a series of dramatic changes in the 1970s. Commodity prices rose sharply in the mid-1970s in response to shortfalls in world grain production, devaluation of the dollar, and increased exports to the USSR. Actions in October 1973 and since by the Organization of Petroleum Exporting Countries (OPEC) resulted in sharp increases in the price of petroleum. Prices of agricultural inputs derived from petroleum such as nitrogen fertilizer and pesticides also have risen.

These and other economic forces (e.g., technological change, tax policies, and inflation) have encouraged established farmers to expand the size of their operations to take advantage of scale economies and to increase farm income. Other farmers, especially middle size operations and beginning farmers, have been confronted with sharply higher capital requirements as land values and other input costs have risen faster than commodity prices. Consequently, the structure of agriculture has continued to change, with fewer farmers producing an increasing share of total output (*Economic Report of the President,* pp. 309–12; see also Martin and Spitze).

Throughout the post-World War II era, cropland has been used more intensively with dramatic increases in land productivity. Rapid expansion in the application of fertilizer and agricultural chemicals has made a major contribution to the increase in land productivity (*Economic Report of the President,* pp. 309–12). However, some of these chemicals have been found to be harmful to the environment and/or human health. And there are doubts about some still in use. In some cases their use has been banned or restricted. Also in recent years, as land has been used more intensively and as marginal land has been brought into production, there have been increasing problems with soil erosion and sedimentation in the nation's waterways.

High petroleum prices and increased U.S. dependence on foreign sources has stimulated interest in the use of grain and biomass for the production of ethanol as an alternative source of fluid energy. Expected growth in ethanol production will place additional strains on the nation's resource base, especially cropland.

As a result of these changing economic conditions, the principal food and agricultural policy issues of the 1980s are likely to be:

(*a*) How can we reduce price and income variability in a growing and more interdependent world market?

(*b*) To what extent will government protect returns to land and other fixed resources?

(*c*) How can we reconcile the private and social costs and benefits of conservation and environmental concerns?

(*d*) To what extent will agricultural output be devoted to ethanol production?

(*e*) What level of financial support will be given to agricultural research?

The papers in the "Proceedings" section were presented at a joint session of the AAEA and the American Economics Association at the annual meeting of the Allied Social Science Associations in Denver, Colo., 5–7 Sep. 1980.

Marshall A. Martin is an assistant professor in the Department of Agricultural Economics, Purdue University.

Purdue Agricultural Experiment Station Journal Paper No. 8203.

(*f*) How will public policy be used to shape the structure of agriculture?

This article provides an interpretive summary of these policy issues and tries to reconcile the interplay and conflicts among them.[1] The primary focus of the discussion is on the implications for future land policy.

Price and Income Policies

Despite recent growth in foreign demand which tends to be price elastic for a particular country such as the United States, the short-run demand for U.S. farm products is still price inelastic. Greater dependence on foreign markets can contribute to increased domestic price and income variability. U.S. export demand can vary due to changes in world agricultural production, changes in exchange rates, or decisions made by marketing boards or authorities in centrally planned economies (Spitze and Martin; Schuh; Robinson).

Wide swings in product prices not only result in fluctuations in farm income, but also give erroneous production and consumption signals. Farmers have greater difficulty formulating optimal production decisions. This results in inefficient resource allocation. Price uncertainty also affects consumer behavior and can lead to consumer unrest, especially in periods of sharply rising prices.

In a market economy, changing relative prices are necessary to allocate production and influence consumption. The question is: How much price and income stability is economically, socially, and politically desirable?

Several price and income policy innovations were adopted in the 1970s. The Agriculture and Consumer Protection Act of 1973 introduced a two-tiered government price and income support system. Target prices have been used to provide some income protection by means of deficiency and disaster payments. Loan rates provide a price floor. They are used to determine the value of nonrecourse loans for eligible farmers and are utilized in operational rules for release of grain from the farmer-owned grain reserve.

Although the target price levels have been adjusted twice by Congress since the passage of the Food and Agriculture Act of 1977, the basic legislative intent is to adjust target prices based on changes in per unit costs of production. The 1977 Act also replaced the historical farm acreage allotments with a voluntary set-aside procedure based on current plantings.

Another major policy innovation in the 1977 Act was the concept of a farmer-owned grain reserve. The primary objectives of the grain reserve are to help stabilize commodity prices and to help insure adequate supplies for export sales and food aid. Eligible farmers, after receiving a nonrecourse loan, may elect to store their grain for up to three years and receive a prepaid storage payment and some interest and farm storage loan concessions. Farmers retain ownership of the grain and make the final marketing decisions but can be influenced by penalties. The grain reserve program provides farmers with incentives to store in periods of low prices for later sale when prices rise. A release and call price procedure based on percentages of the loan rate is used to encourage gradual release of the grain from the reserve back into normal market channels. (For a detailed discussion of farm commodity legislation in the 1970s, see Tweeten, Martin and Spitze.)

The demand for grain for export sales and for ethanol production is expected to expand in the 1980s. At the same time there are likely to be additional restrictions on the use of agricultural chemicals as well as efforts to encourage soil conservation measures resulting in a more modest growth in the supply of agricultural products. Consequently, commodity prices are likely to rise, thereby reducing the likelihood that set-aside measures will be imposed in the decade ahead.[2] Target prices and deficiency payments will become relatively less important as policy instruments.

The major price and income policy issue of the 1980s likely will focus on the level of the loan rates and the use of the grain reserve to stabilize prices. Loan rate levels will be de-

[1] In analyzing a framework for food and agricultural policy for the 1980s, Lee describes a similar set of emerging issues.

[2] Some preliminary estimates by Jerry A. Sharples, using FEEDSIM, suggest that a high rate of export demand growth—continuation of rates in the 1972–80 period—and low growth in productivity, 1.5 and 0.4 bushels per year growth in average corn and soybean yields, respectively, would result in substantially higher real corn and soybean prices in the 1980s. Both corn and soybean prices would increase at an annual rate of 13%. He assumed a 2% annual growth in corn demand. This could be higher depending on expected growth in ethanol production. About 20 million additional acres would be required for these two crops alone by the mid-1980s. Sharples estimated that even if yields increased at the rate experienced since 1960 (2.0 and 0.5 bushels per acre per year for corn and soybeans, respectively), growth in domestic demand at the same rate as in the 1970s, and export growth at half the actual rate of the 1972–80 period, real corn and soybean prices would increase at an annual rate of 4%–5% and about 4 million additional acres would need to be brought into corn and soybean production by the mid-1980s. See Holland and Meekhof for more detail on the FEEDSIM model.

termined largely by budget considerations, relationship to world market prices, changes in production costs, influence on the acquisition and release of grain in the farmer-owned reserve, and possible structural impacts.

The public's conception of the price and income problem also may change. Prior to the 1970s, the perceived problem was low and falling farm prices and income. The public was willing to provide some farm price and income support. During the 1980s, the public's main concern likely will be directed toward rising food prices for consumers and rising production costs for farmers. The legislative focus probably will be on means to stimulate production, enhance competitive pricing to help restrain inflation, and encourage export sales.

Environmental and Conservation Issues

Our present problems of environmental pollution result from more intensive use of our natural resources, particularly land and water. And a better educated, better informed, more affluent, and more mobile population has demanded improved standards of environmental quality. These pressures led to congressional approval in the 1970s of various new regulatory agencies and laws (see Paarlberg).

Sediment is the largest single pollutant of surface water. Soil erosion losses have been estimated as high as 4 billion tons a year, with one billion tons reaching the major rivers. About half of this erosion is from agricultural lands. Annual soil losses from cropland range from one to 100 tons per acre, depending on the crop system, management practices, rainfall, soil characteristics, and topographic features (Wischmeier).

Sediment is also an important carrier of plant nutrients, pesticide residues, and infectious agents. Plant nutrients from soils, animal wastes, and fertilizers have contributed to local problems of excess aquatic growth (eutrophication) and nitrate contamination of ground water supplies.

Approximately one million acres of prime farmland (0.3% of cropland currently in production) are converted each year to urban uses (Brubaker). Consequently, farmers will need to use more variable inputs, such as fertilizer and pesticides, and/or bring additional marginal land into production as they seek to expand agricultural output to meet the expected growth in export and domestic demand. This will exacerbate problems of soil erosion and sedimentation.

Only about 30% of the sediment load comes from cropland where changes in tillage systems can reduce sediment loss. The greater portion of the sediment load comes from noncropland, e.g., construction sites, grazing land, and waste land (Paarlberg).

Wade and Heady estimate that it would cost $13.4 billion annually to reduce the sediment load from cropland by 90%. However, such reduced tillage and conservation efforts on cropland would leave the noncropland unaffected. Consequently, the total sedimentation load would only be reduced by about 23%.

There is little economic incentive in the shortrun for an individual farmer to adopt those conservation practices that may reduce short-run production and increase costs, particularly if the land is farmed under a short-run rental or lease arrangement. Consequently, land tenure arrangements often do not fully reflect the externalities associated with current tillage practices. However, as land values and energy costs have risen in recent years, farmers have adopted tillage practices that reduce soil loss and energy use.

In order to internalize the externalities associated with nonpoint pollution, a joint effort among farmers and the government will be necessary. Some type of governmental incentives will be needed to encourage farmers to discontinue fall plowing of certain soils, use contour farming techniques, and take marginal land out of production. Farmers who follow recommended soil conservation practices could be guaranteed a conservation diversion payment or become eligible for certain farm commodity program benefits. (Benbrook provides an excellent summary of alternative ways to integrate farm commodity programs and soil conservation efforts. He also explores some of the institutional implications.)

Various researchers (Headley and Lewis; Taylor and Frohberg; Cashman, Martin, McCarl) have examined the economic impacts of restrictions on pesticide use. The short-run, farm-level and aggregate losses in production and income are generally small if the use of only one or two of the primary pesticides is prohibited. However, as the number of pesticides banned is increased, production losses increase substantially. In many cases farmers must turn to different crop rotation systems or higher-cost, less effective pest control practices. The irony of potential pesticide bans is

that, given the inelastic, short-run demand for most agricultural products, further restrictions on pesticide use could affect consumers more adversely than farmers.

Environmental and conservation issues are certain to be major policy concerns in the 1980s. Farmers and environmentalists often perceive great differences in their goals and points of view. A reduction in soil loss is in the long-term interest of farmers, consumers, and environmentalists. Alternative ways must be found to equate private and social costs and benefits. A combination of taxes and subsidies can be used to reduce soil erosion and agricultural pollution.

Integrated pest management, biological controls, and better cultural practices potentially can reduce pesticide use and production costs without major reductions in production. Future policy efforts to reduce soil erosion and agricultural pollution will require additional research knowledge on the interface between pesticide use, energy requirements, and soil losses.[3] Also, research efforts on the environmental impacts of continued growth in export and domestic demand for grains should be given high priority.

Energy Policy

Growing scarcity of global energy supplies will present a major challenge to U.S. agriculture in the decade ahead. Scarce liquid fuel supplies and rising prices could significantly alter resource use, cropping patterns, and the level of agricultural production. This could result in changes in relative commodity prices, farm income, food prices, and regional comparative advantage, especially if grains and biomass are used increasingly to produce ethanol.

Such a scenario raises a number of new policy questions. Some are related to conflicts between resource use for food versus fuel production. Others involve the environmental implications of increased use of land, water, and other scarce resources to meet growing food and fuel demands.

Currently, the food sector accounts for 16.5% of total U.S. energy consumption. Production agriculture directly and indirectly uses about 3% of total U.S. energy use. Thus, reductions in energy use in production agriculture will have only a minimal impact on the national energy problem.

About 93% of the energy used in production agriculture is derived from petroleum. Fertilizer composes about one-third of the energy used in agricultural production. Fuel for irrigation and natural gas for crop drying are two other major forms of liquid energy used in agricultural production (Paarlberg).

Various proposals have been made to reduce the amount of energy used in production agriculture, e.g., more crop rotation, less use of nitrogen fertilizer, and less reliance on artificial crop drying. While such practices have merit in certain circumstances, in many cases such approaches would result in lower yields and higher production costs per acre and per unit of output.[4]

The major energy challenge for U.S. agriculture in the 1980s will involve the production of ethanol from grain and agricultural byproducts. Production of ethanol is particularly attractive to grain farmers because it could increase the demand for grain and thereby increase their incomes.

Initially, a gasohol program was viewed by some people as a way to alleviate grain surpluses and eliminate the need to pay farmers to idle farm land. Increasingly, it is being viewed as a way of increasing farm income, generating employment, and reducing U.S. dependence on imported oil.

Feed grain and wheat set-aside and diversion acres totaled 16.7 million and 10.5 million acres in 1978 and 1979, respectively. This acreage could have produced about 972 million bushels of grain in 1978 and 550 million bushels in 1979. At a conversion rate of 2.6 gallons per bushel, this implies 2.5 and 1.4 billion gallons of ethanol in 1978 and 1979, respectively, or an average of 1.95 billion gallons per year. This represents about 2% of annual gasoline consumption in the U.S.

Meekhof, Tyner, and Holland have examined the economic implications of eliminating all set-aside and diversion programs and using a price guarantee for major grain crops. They assume that the government would buy the grain at or above the loan rate and subsidize its

[4] A rational energy policy in a market economy suggests that efforts to reduce energy use in agricultural production should reflect changes in relative prices and should not be based on an "energy theory of value" that only seeks to minimize the number

conversion into ethanol. The subsidy would make the wholesale price of gasohol roughly equivalent to unleaded gasoline.

Alternative levels of ethanol production were analyzed ranging from 1 to 4 billion gallons of ethanol (0.4 to 1.5 billion bushels of corn). Levels of 1 to 2 billion gallons had relatively little impact on corn and soybean prices, production, exports, and domestic disappearance. Levels of 3 to 4 billion gallons tended to increase corn prices substantially, reduce corn exports, reduce domestic disappearance, and increase price instability of both corn and soybeans. Increased supplies of distillers dried grain, a high protein by-product, reduced the demand for soybeans thereby reducing the acreage planted to soybeans.

While the production of alcohol from agricultural crops may be politically and economically attractive, there are also potential problems. Unless the cost of alcohol production becomes more competitive with that of petroleum, large federal and state subsidies would be required to encourage gasohol production. Currently these subsidies are about $0.50 per gallon of ethanol. In the context of the Meekhof, Tyner, and Holland study, this would imply a total annual gasohol subsidy of $0.5 to $2.0 billion. For comparison, total government farm program payments in 1978 were $3.0 billion—the highest level since the late 1960s and early 1970s.

Another concern raised by some is the potential conflict of food versus fuel production. Brown argues that there could be a massive diversion of agricultural resources to energy production at a time when efforts to expand world food output are losing momentum, food prices are increasing, and malnutrition is increasing in some less developed countries. However, most of the poor people in the less developed countries are employed in agriculture and could benefit from higher farm commodity prices if their governments do not follow cheap food policies which distort market prices.

Current U.S. ethanol production facilities are designed to use corn as a feedstock. During the 1980s other feedstocks are likely to increase in importance. Diversification of feedstocks to lower-cost, nonfood sources should reduce the conflict of food versus fuel. Also, there should be less soil erosion as biomass replaces corn as the principal feedstock.

Major efforts to stimulate gasohol production in the decade ahead will require reexamination of current farm policy including supply management programs, export policy, food aid efforts, and price stabilization policies. A major challenge to policy makers will be to provide subsidies and policies that are sufficiently flexible to provide adequate incentives to expand food and fuel production without causing significant land and environmental deterioration or undue hardships on low income consumers, particularly in the less developed countries.

Structural Debate

The structure of American agriculture has been a source of concern for many for several decades. Structural change has been occurring among the agricultural marketing industries as well as in the economic organization of agricultural production. The marketing concerns include imperfect competition, increased concentration, and market power. These will continue to be important policy issues in the 1980s but lie beyond the scope of this article.

The most commonly cited structural problem is farm size and the concentration of agricultural production (Stanton). Since 1950 the number of farmers in the United States has declined by half and the average farm size has more than doubled (USDA). Gardner (1980) has shown that in 1978 the smallest 40% of U.S. farms accounted for less than 2% of sales, while in 1940 the smallest 40% produced 8% of the sales. In contrast, the largest 20% in 1978 produced 80% of sales, while in 1940 they produced 64% of sales.

Many factors have contributed to structural change. They include: technical change in farm production, changes in product and factor markets, tax laws, macroeconomic policies, the competitive nature of the sector, and farm commodity programs (Gardner 1978).

Several studies have documented the distributional implications of farm commodity programs on farm structure (Bonnen; Schultze; Lin, Johnson, Calvin). Because subsidies or deficiency payments are based on production, larger farmers receive larger payments. In 1978, almost half of the $2 billion of deficiency payments went to 10% of the farm program participants—those with larger farms. By contrast, 50% of the farms—the smaller units—received only 10% of the payments. Thus, farm commodity programs have

increased the inequality of the distribution of income in agriculture. What is not clear is the extent to which commodity programs have changed farm structure.

Some argue that price support programs increase average size and concentration of farm production units. It is hypothesized that high price supports generate windfall gains for the larger producers enabling them to outbid smaller producers for land. However, conceptually, the optimal size of a competitive firm (assuming perfect markets) is independent of product price. With imperfect capital markets, small operations may reap less benefits than larger ones from high price supports.

It has also been argued that farm programs reduce price risk (Pope and Gardner). Risk reduction can increase specialization. Net farm income as a percentage of total income is greater on larger-scale operations. Thus, price stabilization by means of farm commodity programs could encourage a shift to larger-scale, specialized farms.

On the other hand, it has been argued that farm commodity programs make it possible for smaller, higher-cost farmers to stay in business (Gardner 1978). Price supports help cover variable costs and increase the returns to fixed resources. In fact, this has been one of the historic justifications of farm programs.

In the 1970s there was considerable rhetoric to reduce payment limitations. Few participating farmers (0.2% in 1978) have been affected by payment limitations. Efforts likely will continue to limit payments to larger producers. Alternative arrangements include graduated target prices which favor small producers or even no target price support for the larger producers.

The level and stability of commodity prices may influence future structural change, e.g., price support programs can result in higher land values and alter land ownership patterns (Boehlje and Griffin). However, tax policy, credit policy, and the rate of technological change may have greater impacts on future changes in farm structure than farm commodity programs.

Reconciling the New Policy Agenda

Efforts to reconcile the policy objectives and issues raised in this article all impinge on changes in land policy. Thirty years ago Schultz first noted the declining relative economic importance of agricultural land as new production technologies were being adopted. A continuing stream of new energy-and-land-saving technologies will be necessary in the decade ahead if growth in agricultural output is to match the expected expansion in agricultural demand without major increases in real commodity prices. Even then, agricultural land policy will be an important policy issue. (Other related land policy issues include foreign and corporate ownership and the continued shifting of prime agricultural land into nonagricultural uses.)

Restrictions on pesticide and fertilizer use to meet new environmental standards tend to reduce land productivity. At the same time, expanding export demand coupled with efforts to produce ethanol derived from energy crops is encouraging expansion of agricultural production and bringing more land into production. This increases the threat of further soil erosion and environmental pollution.

Rising land values have exacerbated farm structure problems (USDA). Beginning farmers are finding it increasingly difficult to acquire sufficient capital to enter farming. Established farmers are confronted with complicated estate-planning problems and potentially high capital gains taxes. Future increases in real commodity prices will result in even higher land values and further structural change.

The challenge to researchers and policy makers is to develop simultaneously a new conceptual framework and new institutional arrangements to deal with the various issues on the emerging food and agricultural policy agenda of the 1980s. Historically, agricultural policies have been analyzed and legislation has emerged in a rather eclectic fashion. And, existing government agencies and institutions were designed to cope with problems of excess capacity and agricultural surpluses, not problems of resource scarcity.

Efforts to expand agricultural production to meet growing food and energy demands without causing serious environmental damage will require a much more integrated policy approach at the federal, state, and local levels. Land ownership and its use is likely to form the crux of the food and agricultural policy challenge of the 1980s.

The Farmer-Owned Reserve: How Is the Experiment Working?

William H. Meyers and Mary E. Ryan

The volatile behavior of grain markets in the early 1970s sparked discussions and research on policies to stabilize grain markets and assure food security. The U.S. farmer-owned grain reserve, instituted in 1977, is an outgrowth of those debates and studies. The reserve has functioned for three years, and a preliminary appraisal can now be made. In this paper, we briefly review the background and provisions of the program in sections one and two; focus on farmers' response to the program and implications for grain markets in sections three and four; and finally, look at problems and prospects for the future.

Background

Instability has become particularly acute in the U.S. grain economy because of the increasing level and variability of U.S. exports, the insulation of important foreign markets from world price fluctuations, and the reluctance of the United States to erect trade barriers to protect domestic markets. Thus, good and poor growing conditions around the world and policy shifts by trading partners and competitors have a destabilizing impact on U.S. grain markets. Because weather and other nations' policies are beyond the control of the United States, other means must be sought if the government desires to alleviate the consequences of destabilizing influences. The literature is rich with studies on the welfare effects of stabilization and on national and international stabilization schemes (Houck and Ryan). Our purpose is not to debate these issues or alternatives but to study the one stabilization program that has been given a trial run.

The U.S. farmer-owned grain reserve (FOR) was instituted for wheat and rice on 4 April 1977, after several weeks of intensive planning by the Carter administration. Although the administration acted under authority of existing legislation, Congress affirmed the action by mandating a producer-owned program for wheat and rice and by authorizing a similar feed grain reserve in the Food and Agriculture Act of 1977 (Johnson). These actions made the FOR the first serious U.S. experiment with a managed, national reserve program.

In making annual decisions about the grain reserve and other crop program provisions, the administration's goal is a total grain carryover of 6%–7% of world consumption. Currently, this means targets of about 1,100 and 1,500 million bushels for wheat and corn, respectively. In addition to the FOR, the other major program for managing grain supplies is the acreage set-aside. The annual nonrecourse loan and concessional export programs are also part of the package. Under current market conditions, the FOR has a central role because, among these instruments, only it can provide some protection against shortages.

Program Provisions

Nine-month, nonrecourse loans and three-year FOR loans are both available to eligible farmers (those in compliance with crop programs) at the loan rate specified for the crop under contract. Farmers retain ownership of grain used as collateral for such loans. There the similarities end. The major added benefit of the FOR is an annual storage subsidy payment approximately equal to commercial storage costs in major grain-producing states. Since March 1978, FOR loans have also been interest-free after the first year. The interest

charge was waived completely on 1979 crop contracts signed after the 1980 embargo of grain shipments to the USSR.

The major added constraints are those that control the redemption of reserve grain. The nine-month loans may be redeemed at any time. Voluntary redemption of FOR grain is permitted only after farm prices reach a specified "release level." After the second consecutive monthly release, storage payments may be suspended.[1] Redemption is mandatory when farm prices reach a specified "call level" or the contract expires. If the loan is not repaid within a specified period (currently ninety days) after it is "called," the grain is forfeited to the Commodity Credit Corporation (CCC). Although the initial loan rate is fixed, the release and call triggers for all contracts are a fixed percentage of the current loan rate, which normally increases over time. The minimum release price for CCC-owned grain is currently 5% above the call level of FOR grain, making CCC inventories a reserve of last resort.

Initially the FOR option was available to a farmer only after his nine-month loan matured. This requirement was relaxed selectively in 1978 and finally was removed completely for all crops in October 1979. Now direct entry to the reserve is permitted except when it is in "call" status or has reached a quantity limit that may be set by the Secretary of Agriculture. This change is important, because it makes reserve quantities more responsive to current market conditions.

In summary, a flexible set of incentives and disincentives is designed to induce farmers to place grain in the reserve when market prices are near or below the release level and to redeem grain when prices are between the release and call levels. The government has no control over the farmer's decision to sell or hold the grain after it is redeemed, although in many cases a cash sale may be required to repay the loan. The FOR participant sacrifices some control over the reserve grain in exchange for a substantial reduction in carrying cost and risk.

Farmer Response

Farmer response to the FOR program involves decisions on whether or not to participate, the level of grain placements, whether or not to redeem grain when it is released, and the amount to be redeemed. A farmer's placement and redemption decisions are influenced by the program provisions, grain use options, price expectations, storage costs, and factors that affect risk-bearing ability.

An aggregate response of farmers to the reserve program can be conceptualized based on the factors influencing the individual decision (Meyers and Jolly). Placements are likely to be small at prices near the release level and increase monotonically as price falls. Similarly, for prices above the release level, redemptions are expected to increase as price rises. These price-quantity relationships add a new component to farm inventory behavior, related to but quite different from demand for "free" stocks. Very little is known about the parameters of these relationships, but it is clear that the response elasticities are influenced by program provisions and farmer expectations.

Annual data on wheat and corn reserve operations provide evidence of farmer response as program provisions and market conditions have changed (table 1). By the end of 1977/78, substantial quantities of both grains had been placed in the reserve, although early placements were sluggish as farmers waited for nine-month loans to mature.

Wheat placements were small in 1978/79, when prices were closer to the release level, and 1978-crop wheat was not eligible for direct entry. Wheat was released in May 1979, and storage payments were halted on 30 June. More than 200 million bushels were redeemed (most before loan and trigger levels were raised in January), but substantial quantities remained in the reserve without the benefit of storage payments. Prices during the heavy release activity were well above the \$3.29 release level; but after the trigger levels were raised, new placements occurred, and the net decline for the year was 143 million bushels. Wheat loan and trigger levels have been raised substantially for 1980/81, so a few placements are anticipated in spite of a higher price level.

The release and call levels for feed grains were set to span a smaller range than that for wheat, largely to moderate input price variability in the livestock industry. One result of the narrower trigger range is more frequent movements in and out of release status for corn (and even more for minor feed grains).

The average price of corn in 1978/79 was

[1] Payments stop if the difference between state price and loan levels is greater than the difference between the national release and loan levels.

Table 1. FOR Placements, Redemptions, Net Change in Reserves, Prices, and Trigger Levels, 1977/78 to 1980/81

[b] Estimates based on monthly USDA reports.
[c] Due to changing provisions, contracts have differing trigger levels.
[d] The 1978/79 levels prevailed until 7 Jan. 1980.

midway between the release and loan levels, and FOR carryover increased by 225 million bushels. In 1979/80, net placements are expected to be about the same, although the average price is near the release level. In both years placements were large during the first nine months. In early 1978/79, direct entry was temporarily permitted while prices were depressed, attracting more than 400 million bushels to the reserve. Late in the year corn was released for less than two months, and nearly 200 million bushels were redeemed. Corn was released again in October and November 1979, but there were few redemptions.

Direct entry became a general provision of the FOR in October 1979, so placement of 1979 corn began early in the year. The rate of placements increased as local grain markets weakened and more attractive reserve provisions were announced after the January 1980 embargo. Loan, release and call levels, and storage payments were increased moderately, and interest payments were waived completely. However, FOR placements were not sufficient to meet the administration's commitment to offset the market effects of the embargo. In April, FOR loans were offered with interest to farmers who did not participate in the 1979 set-aside. By the end of June 1980, about 350 million bushels of corn had been added to the reserve. In July, as prices rose in response to poor weather conditions, corn was released for the third time. Current estimates anticipate redemptions of 140 million bushels by the end of the crop year.

The corn reserve is likely to undergo its first real test under shortage conditions in 1980/81, when average price is expected to be above the "first" call level. By current estimates, the corn FOR will be exhausted before October 1981, and CCC stocks will remain intact.

Both wheat and corn farmers have responded to program incentives, and the pattern of their response is clearly affected by changing program provisions and market conditions. Placements were constrained in 1977/78, but in other years have occurred at prices well above loan rates, especially when direct entry was permitted. Redemptions sometimes have occurred at prices well below call levels, but many farmers continue to hold reserve grain in anticipation of higher prices even when storage payments are suspended.

The Secretary of Agriculture has broad discretionary authority over program provisions, which can raise or lower the rate of response.

Yet, program administrators must operate with a substantial degree of uncertainty about farmer response and, consequently, about whether program objectives can be achieved. This uncertainty leads to frequent tinkering with program provisions when the desired response is not forthcoming.

Market Implications

Two major objectives of the FOR are to stabilize price variability within a fairly broad range and to increase the reliability of U.S. supplies for export and domestic use. The FOR adds a price-responsive component to the market and thus increases the elasticity of total market demand when the FOR is open for placements or redemptions. Clearly this has the effect of reducing price variability both across years and within years. By the same reasoning, the FOR increases the elasticity of export supplies. Thus the operation of the FOR creates a fundamental change in the structure of grain markets, which alters the market impact of shifts in government policies and other exogenous shocks. We employ a simple annual model to explore the interaction of the FOR with market supply and demand and to generate a preliminary estimate of the impact of the FOR on corn and wheat markets from 1977/78 to 1980/81.

For comparison purposes, an alternative policy assumption is needed. The 1977 Act provides an alternative policy for feed grains, and we will assume the same for wheat—a nonrecourse loan program with a CCC release level of 115% of the loan rate.[2] All other policy decisions are held constant in this analysis.

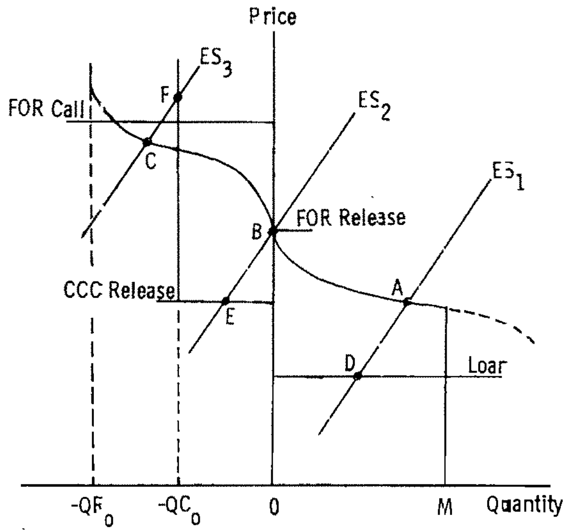
The interaction of the FOR with annual market supply and demand is illustrated in figure 1 and compared with that of the alternative nonrecourse loan program. Annual net placement behavior for the FOR is represented by a truncated "s"-shaped function in the positive quadrant. It is truncated by the constraint on new placements (M) that may be imposed by the Secretary of Agriculture. Annual net redemptions are represented by an "s"-shaped function in the negative quadrant. The level of reserves at the beginning of the year (QR_0) limits total redemption. The alternative program is represented by a perfectly elastic government demand at the loan rate and a perfectly elastic "supply" at the CCC release level. The latter is constrained by the beginning level of CCC stocks (QC_0).

The equilibrium price in this model is determined by the intersection of a stochastic excess market supply (ES_i) with the appropriate reserve stock relationship. If the release price is set at the long-run market equilibrium, the expected excess market supply is represented by ES_2 where free supply and demand are in balance at prices near the release level and there is little FOR activity. In this context, ES_1 and ES_3 represent the variability of excess market supply given world surplus and shortage conditions, respectively. If there is a market surplus, reserves are accumulated by the FOR at prices between the release and loan rate (point A). A shortage in the market leads to redemption and sale of FOR grain at prices between the release and call levels (point C), although the illustration shows that not all sales necessarily occur below the call level.

It is clear that the range of price variability under the FOR program is not determined by the loan and call levels but depends crucially on the factors that determine the response functions. These functions may lie above or below those illustrated in figure 1. For example, if the FOR provisions are attractive and long-term price expectations are high relative to current prices, reserves may accumulate rapidly and hold prices well above the loan rate. If price expectations are weak and the disincentives for holding grain at prices above the release level are large, redemptions may occur rapidly and keep prices well below the call level.

With only the CCC inventory program, the given range of market conditions (ES_1 to ES_3) is likely to generate a wider range of equilibrium prices than that obtained with the FOR. Under the surplus scenario, price would be near the loan rate, more grain would be consumed, and less stockpiled (point D). Because less accumulation occurs during surplus periods, the reserve would in general provide less protection in periods of severe scarcity (point F). There are several caveats to this generalization. First, the extent of divergence between points A and D or points C and F depends on program provisions and the other factors that influence the FOR response func-

[2] The 1977 Act sets the CCC release level for feed grains at 115% of the loan rate if the Secretary of Agriculture does not activate the FOR. This alternative also represents a practical minimum level of government intervention under which government inventories accumulate only through loan defaults and are released as soon as possible thereafter.



ES_t is production plus beginning free stocks less total demand for domestic consumption, exports, and free stocks; M is government limit on new placements; QR_0 is FOR stocks at beginning of year; QC_0 is CCC stocks at beginning of year.

Figure 1. The farmer-owned reserve and alternative CCC programs under differing supply and demand conditions

tion. Second, without the FOR, the administration and Congress would be under greater pressure to raise loan rates and increase crop set-aside when surplus conditions exist. Third, the graphical comparison is static rather than dynamic and does not take into account the effect of reserve stocks on free stock levels or the effect of altered prices on production.

In the dynamic analysis below we continue to hold other policy actions constant but take account of the production response to changing price levels and the effect of reserve stock levels on free stock demand. Although we do not know the position of the FOR response curves, the annual historical observations define points such as A, B, and C on these unknown relationships. From these observed points, we generate points such as D, E, and F under the alternative program by assuming price elasticities for the components of excess market supply.

The five-equation model abstracts from all supply and demand shifters except FOR and CCC-owned stocks. The latter are assumed to influence private inventory demand.

(1) Excess market supply (identity):
$$ES_t = QP_t + QI_{t-1} - QD_t - QI_t$$
(2) Domestic and export demand:
$$QD_t = D(P_t)$$
(3) Ending free stock demand:
$$QI_t = I(P_t, QR_t, QC_t)$$
(4) Equilibrium condition (identity):
$$ES_t = QR_t - QR_{t-1} + QC_t - QC_{t-1}$$
(5) Production response:
$$QP_{t+1} = S(P_t),$$

where P is market price, QC is ending CCC stocks, and QR is ending FOR stocks.

In 1976/77 both FOR and CCC inventories were zero, so our analysis begins in 1977/78. FOR stocks are reduced to zero in each year, and the operating rules for the alternative program are imposed.[3] These changes affect current utilization, free stocks and price; the last influences production for the following year. The price elasticities assumed for consumption, free stocks, and production are −.3, −1.0, and 0.2, respectively.

The effects of FOR and CCC inventories on free stock demand ($I_2 = \partial I/\partial QR$, $I_3 = \partial I/\partial QC$) are important in this analysis, and few empirical measures are available. Clearly if these coefficients are −1.0, the operation of a reserve has no effect whatever on total stocks or on price. Gardner demonstrates with an optimization model that public stockpiling reduces the expected gains from private storage and thereby reduces private stock demand. Empirical estimates of the shift in free stock demand caused by such an expectations effect for CCC inventories range from −.32 per bushel for corn to −.09 per bushel for wheat (Gallagher et al., Baumes and Womack). Because of the wider band between the loan rate and release prices for both FOR and CCC grain under the current program, the expectations effect may well be smaller than the historical estimates indicate. On the other hand, there may be added effect from farm level substitution between FOR and free stocks. The short data series preclude precise estimates of these effects, but the first such estimate by Sharples and Holland indicates an aggregate substitution effect of −.13 per bushel for FOR wheat. They attribute this effect to an on-farm substitution between FOR

[3] To "hold other policies constant," we take the actual year-to-year change in CCC stocks (ΔCCC) as given. (This is necessary to account for special purchases after the Jan. 1980 embargo.) Then,

$$QC_t = QC_{t-1} + \Delta CCC,$$

unless the equilibrium price falls below the loan or rises above 115% of the loan; QC_t increases to "protect" the price floor and decreases to "protect" the release level until reserves are exhausted.

and free stocks, but it also could be partly or entirely a measure of the expectations effect. Our analysis assumes that $I_2 = I_3$ and uses coefficients of $-.2$ and $-.4$ to provide a fairly conservative range of FOR impacts.

The results for the period 1978/79 to 1980/81 are summarized in table 2.[4] For both crops the elimination of the FOR results in a higher price variance, lower total stocks, lower reserve levels, and higher free stocks. Effects on production over this period were relatively small, but the changes in stock levels were substantial. Without the FOR, grain stocks as a percentage of utilization in 1980/81 would approach the levels experienced in 1973/74 for corn and 1974/75 for wheat, and all reserves would be exhausted. As expected, a smaller impact is obtained when a higher rate of substitution ($-.4$) between reserves and free stocks is assumed.

In the case of wheat, average annual stock levels are 200 to 240 million bushels lower without the FOR, and free stocks are 100 to 200 million bushels higher. Average reserve levels with the FOR account for nearly half of total stocks. Without the FOR, reserves are very small, because the lower release price of $2.70 allows reserves to decline in 1978/79. What remains is exhausted in 1979/80. Wheat prices without the FOR are about $.30 lower in 1978/79 and $.50 to $.80 lower in 1979/80, but a sharp rise in prices occurs in 1980/81 as stocks are drawn to near pipeline levels.

Corn without the FOR shows a 180 to 230 million bushel decline in average annual stocks and a 70 to 130 million bushel increase in free stocks. Average reserve levels with the FOR make up nearly half of total stocks. With no FOR, reserves are about 300 million bushels lower on average and all reserves are exhausted in 1980/81. Prices without the FOR are lower in the two years of surplus but rise sharply in 1980/81 to levels above the FOR call price.

The impact of the FOR on average price seems to be significantly greater for wheat than for corn, in part because wheat trigger levels have escalated more rapidly. This is also reflected in the four-year total value of farm production, which was 10% to 15% higher for wheat with the FOR and 2% to 3%

[4] Although 1977/78 was included in the analysis, FOR activity was not significant until the latter half of the year and had little impact on prices or stock levels. FOR placements essentially replaced CCC defaults in 1977/78, so this did affect the realized value of farm production.

Table 2. Stock and Price Levels with the FOR Compared to Estimated Levels under Alternative CCC Program with Different Rates of Substitution between Reserve and Free Stocks ($-.2$ and $-.4$)

	Wheat			Corn		
		No FOR			No FOR	
	With FOR	(−.2)	(−.4)	With FOR	(−.2)	(−.4)
	(million bushels)

Farm value of production 1977–80[a]	28.5	24.8	25.6	70.3	68.6	68.9

[a] FOR grain is counted in the year of sale; wheat reserves remaining in 1980/81 are valued at the release price.

higher for corn. Higher farm prices are partially offset by lower deficiency payments for wheat in 1978 and 1979 and for corn in 1978. Payments over this period under the alternative policy would have been $400–$700 million higher for wheat and about $300 million higher for corn.

The price-enhancing effects of the FOR during surplus periods benefit all farmers regardless of program participation. Similarly, all farmers feel the price-depressing effects during periods of shortage when reserves are released. FOR participants gain added benefits through their storage operations, because they are able to carry grain from surplus to shortage periods at little or no cost. According to a recent survey of corn and wheat farmers, the benefits of participation accrue primarily to large farms with large cash grain operations (Meyers, Jolly, Ryan).

For the purpose of clarity, a simple model was used for this analysis. The model could be refined to include cross-commodity effects among grains and other crops and the interaction with livestock markets. On balance, the omission of these factors results in relatively conservative estimates of the FOR impacts.

Problems and Prospects for the 1980s

The farmer-owned reserve experiment has shown that this kind of cooperative reserve program, combining private incentives and public intervention, is a viable approach to stabilization. It has reduced price variability and increased annual carryover stocks consistent with stabilization and security objectives. Intended or not, it also has raised the average price of wheat and the farm value of production for wheat and corn over the period. The price-enhancing effect of the program in surplus years has shifted some of the income support burden from the target price system (the taxpayer) to the market (the consumer). The consumer, in turn, benefits from lower prices in years of shortage. The experimental phase will not be complete until it is tested during a period of shortage. In addition, there remain operational issues and questions of objectives to be resolved.

As with any new program, there have been numerous implementation problems with the FOR. With experience, such problems are being rectified. A major constraint to the responsiveness of reserve placements to market conditions was removed when direct entry was made a general provision, effectively severing the link between the annual loan and FOR programs. One remaining potential constraint is the requirement that participants be in compliance with announced set-aside programs. This can leave the FOR with an inadequate operating base when set-aside participation is low, as was the case with corn in 1979/80. The release and call mechanism has yet to be tested under severe shortage conditions, although 1980/81 corn may be such a test. It may be necessary to impose additional disincentives to encourage redemption between the release and call levels and insure an orderly release of grain within this range of prices.

A key issue is whether the FOR will be used strictly to stabilize prices around the long-run market equilibrium or to raise equilibrium price levels. The wheat analysis indicates a tendency toward using the FOR as a price and income support mechanism. Some policy leaders have supported using the release price to keep market prices in line with farmers' production costs. Depending on the choice of "production costs," such a policy could transform the FOR into a high price support mechanism if release levels are set above market equilibrium prices. It would move distinctly away from the direct payments approach and return to increased reliance on consumers for supporting farm income. It would require greater reliance on acreage controls and threaten to revive all the well-known problems associated with supporting prices above market equilibrium levels.

A pure stabilization approach to the FOR would require setting release levels near long-run market equilibrium prices while continuing to use direct payments, if necessary, for income support. There would be little or no need for a set-aside program. Of course, these approaches do not differ if long-run market conditions are such as to keep equilibrium prices rising with farm production costs.

Finally, there is the question of size and stabilization objectives. The anticipated emptying of the corn reserve in 1980/81 indicates the limited protection afforded by current stock objectives. Moreover, the current reserve mechanism does not provide any assurance that the United States can respond to emergency food needs of the third world in periods of scarcity, and a special emergency wheat reserve for this purpose has awaited congressional approval since 1977. If the

United States continues to operate the reserve unilaterally, it must decide how much stability and food security will be provided and for whom. Will world prices be stabilized or only U.S. prices? Will the supply security objective include all export customers, a select few, or only the United States? Answers to these questions will determine the required size and cost of the reserve and whether or not it is necessary to adopt other measures, such as export management (Cochrane, Martin, Spitze) to achieve the objectives.

There is every indication that a farmer-owned reserve in some form will continue to be an important instrument in food and agricultural policy in the 1980s. It offers a mix of stabilization and security benefits and a blend of government and private control that have won broad support in Congress and is palatable to many farmers. But the FOR is a flexible policy instrument. How the program is used will depend to a great extent on who controls the program and what objectives are established to guide its operation.

A Framework for Food and Agricultural Policy for the 1980s

John A. Schnittker

Four broad subjects, or areas, will dominate food and agricultural policy discussions during the 1980s. They will not necessarily be prominent in the debate on the 1981 farm bill, however, because they may develop slowly during the decade. The areas are as follows:

(*a*) A perceptible shift toward commodity shortages and rising real prices for agricultural commodities as the norm for the food and agriculture sector. The food and agriculture policy agenda during the 1980s will be determined largely by the way this situation develops.

(*b*) The declining role of price and income supports and production-adjustment programs, long the mainstream of federal agricultural policies. They will remain in the law but will be greatly diminished in importance. Occasional commodity surpluses may still require attention, however, in a general climate of strong demand and rising real prices for food and agricultural products.

(*c*) How to cope with shortages and rising real commodity and food prices to the satisfaction of farmers, domestic consumers including new users, foreign customers, and budget planners will become the mainstream of domestic and international agricultural policy.

(*d*) A grab-bag of concerns, including how to get beyond rhetoric in the discussion of farm size, farm and rural life, and other areas that have been collected under the heading of farm structure; how to bring the price support and marketing programs for dairy products closer to the mainstream of food and agriculture policy; how to manage the increased demands on land and water and reinvigorate land and water conservation programs at the same time; how to get other nations to provide a portion of the world's grain reserve; and a host of agricultural policy trivia including how to estimate cost of production, what to do with the estimates, how to set loan and target prices that farmers will have little interest in, how to operate our reserve programs without making them entirely incomprehensible, whether the food stamp and school lunch programs are agricultural or welfare programs, how to proceed on various food safety issues in the wake of the abortive nitrite experience, among others.

John A. Schnittker is President, Schnittker Associates, Washington, D.C.

The Shift to Commodity Shortages

The 1960s and 1970s were dominated by commodity surpluses, with occasional mild remissions and one three-year period of severe shortages. Even in that period, the real price of corn in the U.S., for example, rose slightly, as did the index of prices received by farmers for farm products marketed. During the 1970s, food price increases became a significant factor in overall inflation for the first time in the twentieth century, apart from war periods.

My view of the world in the 1980s, assuming it is relatively peaceful and modestly prosperous, is that demand for agricultural resources and commodities, especially land, technology, livestock products, and grains and oilseeds, will be very strong. Some developing nations will neglect their agriculture because they have oil to sell; others will eat their agricultural successes as rapidly as they achieve them and will need still more food. Rising incomes in relatively advanced developing countries will cause the demand for livestock products to outstrip their own food production. The demand for grain and other agricultural products for use as energy and sweetener feedstocks will add to an already strong overall demand.

Real prices of agricultural products seem likely to rise under such circumstances, both to help ration the limited agricultural products among various users, nations, and processes, and to let farmers know that more production is needed. Managing and responding to this phenomenon will represent a continuing chal-

lenge. It will change what agricultural officials worry about from day to day, both in the United States and abroad. It need not require a vast array of new programs or a new army of administrators in the Department of Agriculture, however.

Price and Income Supports and Production Adjustment Programs in an Era of Commodity Shortages

These programs have been the mainstream of food and agricultural policy for many years, but they will not retain that position during the 1980s. Experience from the 1970s tells us that conventional price and income support and production adjustment programs will be mothballed, not discarded, under the circumstances postulated for the next decade. If conditions change for a few years for one commodity or another, some of these programs may be needed again. The basic farm program instruments, such as price support loan and purchase programs, authority to limit acreages of major crops, and to store and later dispose of surpluses, probably will be continued for a decade or more, even in the economic climate I have suggested. Intense but usually meaningless debates will erupt occasionally in USDA and among farm groups over loan and target price levels and acreage diversion programs. They seldom will be important.

Managing Shortages of Agricultural Resources and Commodities

This area will become the mainstream of food and agriculture policy during the 1980s. Its principal components will be grain reserves and export arrangements. Adoption of a program in 1977 to isolate certain amounts of grain from the market until prices rise well above support levels represents an important beginning toward managing shortages in the 1980s. That program is now the principal price support program for grains, a fact that is not yet clear to farmers or to the marketplace. It helped stabilize prices in 1980 and will provide the government some time to prepare for the more direct actions that may be required to help achieve national economic objectives in case commodity shortages are as severe and as chronic in the 1980s as surpluses were in the 1950s, 1960s, and half the 1970s.

U.S. experience in managing commodity shortages in peacetime has been chaotic. It began in 1973 with official misstatements of actual U.S. policy regarding the possible use of export controls. Promises were made never to limit exports, followed by imposition of export embargoes (the worst form of export restraint) for certain agricultural commodities when shortages appeared to be more severe than had been expected.

The ability and willingness of the United States to limit the volume of exports of feedstuffs, especially to countries with high meat diets, and the means by which such limits would be applied may become key elements in maintaining adequate supplies of grain for all domestic uses at reasonable and competitive prices: (*a*) if the demand for grain generally outpaces increases in production; and/or (*b*) if poor harvests in a number of seasons dissipate reserve stocks in the 1980s.

Since it has long been U.S. policy to expand the volume of agricultural exports, it will require a major effort by the U.S. government and by farm groups to address the question of limiting exports rationally while maximizing export earnings from reduced shipments. The relatively recent introduction of domestic price stabilization to the list of objectives governing U.S. agricultural exports and the addition of sweeteners in the 1970s and ethanol production in the 1980s as high priority domestic uses for grain are a threat to the achievement of the traditional objectives of export policy. The recent use of agricultural exports as a diplomatic tool has taken us even further from past hopes and practice in regard to farm exports.

In this climate, the development of arrangements with a number of countries under which the United States would agree to supply a certain volume, but not unlimited quantities, of food exports seems likely to become a major element of agricultural and trade policy. Such an effort would lead inexorably to limits on the volume of exports under certain circumstances as a matter of policy.

The United States has had a policy for many years to limit exports for economic, national security, and foreign policy reasons. Policy in respect to the use of restraints on agricultural exports was stated in the report dated 25 May 1976 of the Senate Committee on Banking, Housing, and Urban Affairs (to accompany S. 3084), and the report of the House of Representatives Committee on International Rela-

tions dated 2 September 1976 (to accompany H.R. 15377). As stated in the Senate report:

> Under the Export Administration Act, it is expressed U.S. policy to use export controls, including controls on agricultural commodities, for both foreign policy and national security purposes, as well as for purposes of protecting the domestic economy from the excessive drain of scarce materials and reducing the serious inflationary impact of foreign demand.

This bipartisan policy was informally ratified during the 1976 presidential campaign. Candidates Carter and Dole emphasized their determination to avoid the use of export controls on agricultural products wherever possible, but cited the need to use such controls whenever the national interest required it or when serious shortages threatened undue inflation in the United States.

The language of the Export Administration Act seems to provide for authority to limit the export of agricultural commodities, using supply or price stabilization criteria. However, the wording of the Act is ambiguous, stating that exports may not be limited for that purpose if supplies of the commodities in question exceed domestic needs. A practical interpretation of the Act would require the Secretary of Agriculture to make allowances for expected export levels before judging if the remaining supply is adequate for all domestic uses, presumably at acceptable prices. This language will require early clarification if the conditions I have described for the 1980s prevail.

It may be necessary sometime during the 1980s to determine and announce the conditions under which agricultural exports will be limited on a continuing basis in pursuit of domestic price stabilization objectives and a fair apportionment of our export supplies among all claimants, including adequate supplies for feeding and industrial uses in the United States. This would require a fundamental modification of our policies and our rhetoric on free and unlimited exports and of our position as a reliable residual supplier. It would precipitate a big political fight.

Our methods of pricing agricultural exports surely would come into question under such conditions, as larger export earnings become essential and possible. Relatively short supplies will increase market prices, and that would add to export earnings through the market. However, the possible need to think the unthinkable and to design procedures for selling our products into a very demanding world market at a premium over prices prevailing in the United States should not be overlooked. I do not refer here to some kind of federal export board or corporation. Such a procedure is out of character with our history, is demonstrably beyond the ability of our government to manage, and is not needed because present law and existing private marketing institutions could quickly adapt to modest revisions in our export marketing methods.

Other Policy and Program Issues

Farm structure is important even if the results of its consideration are mostly talk and the thrill of participation. Perhaps some steps can be taken in the 1980s to get this issue beyond rhetoric and to help a few thousand farmers. We have known for thirty years that big farmers get most of the commodity program benefits, that displacement of small farmers often was accelerated by federal programs, that a very small number and percentage of farmers market most of our food commodities, and that certain people are more aggressive than others in using debt and the tax laws to ease their relatives and neighbors out of farming. The clock will not be turned back by policy measures on fifty years or more of farm technology, farm consolidation, and the abandonment of small towns and other rural infrastructure built by our grandfathers. But incentives that speeded farm consolidation can be limited or removed, help can be provided for a few more young and small farmers, old farmlands can be reclaimed, and new energy and fertilizer sources can be encouraged. Such measures are important, but they will have little relationship to commercial agricultural production in the 1980s.

Neither the price support program nor the marketing order program for dairy products is in harmony with the programs for other major agricultural commodities. Since the 1960s, continuous efforts have been made by Congress and several administrations to reduce the level of government activity affecting major commodity markets, especially grains and cotton. Restraint in increasing price supports has resulted in market prices generally above support prices for most other commodities. These program changes were made to take account of the changing structure of these producing sectors and of gains in production

efficiency, to compete more actively for world markets, to provide more opportunity for market forces to perform their traditional functions, and to insulate the overall economy from inflationary impacts arising from agricultural price and income support programs.

Congressional action and administration lethargy in recent years have moved dairy policy in the opposite direction. Milk programs are visibly inflationary, and this needs to be remedied in the 1980s. It is a curious anomaly that when grain and soybean prices move well above support levels, federal programs are shelved and forgotten; but when milk prices do the same, it is taken as a signal to raise support levels. It will require a hard political fight to modernize the milk programs some time in the 1980s, but it needs to be done.

A Framework for Analyzing Agricultural and Food Policy in the 1980s

Dale M. Hoover

In a recent paper my colleague E. C. Pasour presented an incisive review of the effects of recent public policy in agriculture. He noted that there have been large transfers from consumers to producers, that these benefits have tended to be concentrated among farms with larger-than-average sales, that benefits frequently have been capitalized—leaving present farmers with little benefit but vulnerable to losses if the programs are given up, and that deadweight losses occur as farmers use resources trying to capture program rents. He goes further to note that government's activities may be destabilizing rather than stabilizing, and that frequently there will be undesired and unintended secondary effects on the economy.

Pasour's paper grows out of a policy framework that is familiar to economists: welfare for a given pattern of resource ownership can be maximized by market activity where competition exists. In some but not all cases, imperfect government can improve on imperfect markets; and when undertaken, the direction and costs of income redistribution should be known. Rather than repeat his analysis, I will turn to the question of the generation of policy. I will argue that policy can be understood and analyzed objectively by the application of familiar concepts.

The economics of public choice (Buchanan and Tullock, Mitchell) consists of an application of marginal costs and marginal returns concepts to three levels of the public decision process: voting, legislation, and administration. I will discuss the three processes separately and then apply them to current policy issues, first emphasizing producer commodity policies; next, consumer commodity policies; and last, externalities and input policies.

Dale M. Hoover is a professor and assistant head, Department of Economics and Business, North Carolina State University.

This is paper number 6648 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh, N.C.

The contributions of numerous colleagues are gratefully acknowledged.

The Cost and Return Framework of Public Policy

In a representative system voters choose legislators and the executive officer based on their perception of costs and returns. Costs in this system include informing oneself of the positions of the candidates, travel to the polls, and possibly contributions of time and money to campaigns. As in other maximizing behavior, marginal cost will equal estimated marginal return at equilibrium. This leads some citizens to contribute large sums of money and others not to bother to inform themselves and vote. In terms of commodity programs, producers' benefits are more concentrated than are consumers' losses, leading to greater influence of producers on policies than their numbers would justify.

The legislative process also can be analyzed in terms of costs and benefits. A legislator will assess the benefit he hopes to receive in terms of reelection votes and funds from his vote for or against a bill. This assessment is complicated by the fact that votes are traded among congressmen, and a system of grants of power is operated inside the legislature based on past participation in the exchange system. These grants of power included creation of a set of committees each with its own purview, determination of committee membership and officers, and development of operating rules for passing legislation. At any one point in time, power is distributed among congressmen and committees as a function of a previous set of transactions. Thus the structure of committees reflects past power as it affects the difficulty or ease of passing legislation. A committee that deals with consumer (food aid) and producer (commodity) interests and that reflects previous power may be able to reach compromises in committee that would be more difficult if left to less formal vote trading on the floor.

The cost of legislation is measured by the

expenditure of resources and the distribution among the citizenry. The perceived costs are a function of the means used to finance the activity. Until the 1860s, consumers of goods protected by import levies paid for national public services. Import levies are still used to pay for some agricultural price support operations. Another "low-profile means of financing a given transfer is output restriction. Here the consumer pays a higher price for the product than competition would entail, but the costs are hard for the voters to estimate. Still another is the budget deficit that imposes costs through future interest payments on debt and/or inflation.

The executive and the bureaucracy make up the third level of the cost-and-returns analysis. The executive bargains with the legislature by making and withholding appointments as well as through the veto. The president and his cabinet officers may ask for and receive discretionary power over quotas and price supports. While this issue is usually justified in terms of flexibility, discretionary authority is a means of shifting power between the legislator and the executive, and in the long run affects the costs and returns to legislation.

A particular bureau can be thought of as a monopolist supplier of its own specialized services (Niskanen). Sometimes the executive acts to create competition by creating new bureaus and sometimes he tries to appropriate the value of the monopoly to his own reelection through the power to appoint officials. Once created, bureaus take on a life of their own including the drive to survive.

Analysis of Current and Future Policies

Following a series of attempts to restrain production to raise prices and transfer income outside of the U.S. Treasury, the major field crops (cotton, wheat, feed grains) have been "deregulated." Historic acreage allotments have been abandoned (Spitze). Loan rates now provide insurance against low prices, and target prices are employed to determine the level and distribution of direct payments. The most important forces that led to this "market orientation," as it has been called, were (*a*) the gross receipts foregone from high product prices in an era of increasing export demand and (*b*) the costs of developing and maintaining restrictions on production. The pull of world prices influenced the development and gradual increase in direct payments for feed grain crops (1962 forward), producer rejection of marketing quotas for wheat (1964), and use of export subsidies and direct payments for cotton (mid 1960s). Good times allowed direct payments to be discontinued. Speaking loosely, producers freed themselves from restrictions they had chosen earlier.

The major current and future policy question for these crops if export demand declines is the choice between diversion and high market prices versus direct payments to augment farmers' incomes. Producers will favor higher market prices; exporters and consumers, direct payments. Present arrangements do not distort resource use greatly but they clearly favor wheat producers (Johnson), probably explainable by the concentration of the economic importance of wheat in a number of relatively rural states.

Rice and peanut programs have moved toward greater "market orientation," substantially because of the high treasury costs of earlier programs. Rice programs now resemble those for wheat. The peanut program allows the Secretary power to set quotas and two levels of price supports which are lower in parity terms than those mandated earlier (Stucker and Boehm). A surge in demand has led to unexpected increases in exports and left quota holders with about the same benefits as earlier. If program costs stay down, there probably will be little consumer force to further reduce production restrictions. Rivalry among producing regions can be expected to grow if technology continues to affect the regions unequally, perhaps eventually leading to production realignment, as in cotton.

Tobacco is an interesting public choice case. It is rigidly controlled by quotas and price supports, and there is no move toward deregulation. This is the case because consumers have acquiesed in a sumptuary tax equal to about fourfold the farm cost of production (Gardner). Quota owners collect only about 1/15 of this tax. The only future forces leading to reduced control are a possible increase in the elasticity of demand as tastes and technology change, and possibly a divergence of interest among the producing regions and between operators and quota owners.

Policy making for sugar represents a microcosm of agriculture and food policy generally. Consumer prices, producer benefits, protection of refiners, minimum wages, and trade are all involved when new legislation is sought. As

things stand, sugar is subject to less regulation than it has been in decades. Should world prices fall sharply, there will be considerable pressure to reinstitute support prices and direct payments for producers. The current agreement between the administration and Congress is to use tariffs and duties to maintain a U.S. market price of 15.5¢ per pound (*Congressional Quarterly*). As noted earlier, consumers have a reason to press for world prices, perhaps adding direct payments which are paid for by taxpayers and are highly visible. Fewer than 21,000 producer firms are directly affected, but the extent of the loss in revenue per firm could be great, particularly among the larger cane producers. Although smaller in size, beet producers are distributed across a number of western states. The leader in the Senate for producer-oriented sugar policy in the past several years has been Senator Church of Idaho, who is up for reelection this fall.

Classified pricing for Grade A milk has been a part of federal policy for over forty years, after coming into being informally in the 1920s (Buxton). The demand side of the market is the acknowledged focus of the law. This is a sign to most economists that income is being transferred. Most of the transfers taking place under the program are between consumers of manufactured products and consumers of fluid milk. Grade A producers have benefited at the expense of Grade B producers, causing a wholesale upgrading of production. Despite the changes in the structure of the dairy industry, it is probably true that Grade A producers are now receiving substantial rents (Dahlgran). These rents largely have been dissipated through high cost production in response to blend prices and unlimited entry.

Consumers, politically less effective than their numbers of aggregate losses represent, currently are seeking the aid of the courts. The Consumer Nutrition Institute is party to a suit to force a federal order area to allow reconstitution. A fluid product consisting of half fresh milk and half reconstituted milk would lower the price of the product, in essence breaking the classification structure. This is the reason reconstitution has been prohibited or taxed out of existence (Buxton). Even if it is allowed, it is not clear that it will cause a lowering of the fluid milk price in all federal and state order areas. This could lead to pressure to rewrite the legislation.

Price supports (1949) and import quotas (1951) grew out of the side effects of the "surplus" generated by classified pricing. The relationship between quotas and price supports continues. If quotas are increased, price supports will have to be lowered if government stocks are to be kept low. EEC dairymen have not been able to offer greater demand for U.S. agricultural products in exchange for increased U.S. imports of dairy products. Thus it may be some time before these policies are changed significantly.

Food Subsidization

The traditional policy has been to tie income transfers to goods. In the major program, food stamps, the ties have been loosened gradually and are now nearly gone. With the removal of the purchase requirement, food stamps have become an income transfer program. The old arguments to maintain the program in the USDA and under the congressional responsibility of the agricultural committees have less and less force. A further shift from commodities to cash in the other nutrition programs would also contribute to a jurisdictional dispute between the USDA and HHS. If there is a realignment of bureaucratic and congressional responsibilities, there probably will be a decline in the power of agricultural interests because under the present regime important compromises between the welfare lobby and the commodity lobbies are made inside the committee and floor debate is minimized.

Domestic Reserves and Restraints on Trade

The private market can and does provide reserves. Even so there has been pressure to develop publicly held reserves. Producers and the trade have resisted the creation of publicly held reserves in the recent past. In a third attempt in conjunction with the Russian trade suspension and producers fearful of market price declines, the administration has been successful. Aside from a number of other issues and arguments, I believe producers are correct in fearing the government-held reserves may be used to keep price increases from occurring in a period of short supply through the use of subsidized storage. As a focal point of consumer interests, storage beyond the level justified by costs and returns could lead to other restraints on trade. It was

the trade interruptions of the 1970s (Johnson) that led to the 1977 provision tying embargoes to high price supports in an attempt to restrain the administration from responding to consumer pressures to restrict trade. It is likely that the consumer-producer conflict on trade will be one of the important policy issues in the years ahead. Consumer-oriented trade restrictions to the detriment of producers is common abroad (Perrin and Scobie). Perhaps producers' best defense in this country would be a doctrinaire embrace of free trade.

Energy

In extending the favorable federal gas taxation of gasohol to 1992, the windfall profits legislation has also potentially affected agricultural policy. This is an instance in which consumers concerned about energy (commodity) prices and farmers joined forces to increase the demand for a farm product. A 4¢ advantage at the pump for gasohol becomes 40¢ at the ethanol distillery. State gas tax rebates and favorable federal income tax treatment raise the subsidy to over $1.00 in some states (Sanderson). At 2.5 gallons of ethanol per bushel of corn, this translates to a subsidy of $2.50 per bushel of corn. Depending on the efficiency of ethanol production and the real price of petroleum, the price of corn could be increased significantly by the current subsidies. Thus energy policy becomes agricultural policy, at least partially inadvertently.

Other Policy Concerns

While commodity policies dominate public policy there are other important issues: food purity, the environment, and worker safety. The current wave of concern grew out of externalities associated with new chemicals used in production whose side effects began to emerge in the 1960s. While the "public interest" movements can be explained, it is not easy to predict their future power. Having generated a new kind of consumer organization and several powerful bureaucracies (EPA, OSHA, and an expanded FDA), they could remain forceful for some time. Using cost and return factors, I would suggest that the force of the movement will recede as more is known about externalities, the costs and benefits of present procedures are widely understood, and as other policy issues command the attention of consumers. I would expect interest in product purity to persist to a greater degree than with the environment and the safety of farm workers.

Farm input policies have evolved and probably will change slowly in response to new forces. One area of active policy making concerning inputs is the substitution of subsidized crop insurance for an open-handed disaster payments program. This is a contest between farmers and the ASCS who favor the current program, and the FCIC and taxpayers, represented by the administration, who favor insurance. In a similar contest between bureaus, grant research is threatening to reduce the importance of formula funding. In these two contests consumers probably perceive they have little to gain or lose and will be inactive. Producers may be enlisted to support formula funding if they become persuaded that their product or state is threatened by grant funding.

There has been a great deal of attention to "structure" in the past several years. It is possible that it will emerge as an issue in the 1980s but I do not see producer, consumer, or taxpayer interests strongly at stake. "Structure" can refer to some measure of the size distribution of firms, the contractual relationships among input owners (usually called the "control of farming"), and probably to other factors. The current organization of farms may have been affected by previous policies such as price supports, disaster payments (USDA, U.S. G.A.O.), and the general responsiveness of the political system to farmer interests. Even so, the concept of structure is currently so ill-defined that it is ripe to be used as a facade for bureaucratic interest or producer justification for free insurance, income transfers, or some similar program.

Some Concluding Comments

There is a pattern in the policy episodes of the past that we can expect to see in the future. Initially an economic shock occurs that imposes sufficient costs for those affected to expend resources to try to achieve some political action. If legislation is successful, unintended effects and costs gradually show up. Then as these costs mount or as economic conditions improve, the policy is altered to be less restrictive on market forces. After the problem is

substantially "solved," a bureau remains, seeking a new policy to supervise. Even so the major agricultural policies have not prevented the working out of economic forces. They have prolonged the adjustment process and in the case of commodity programs have transferred sizeable amounts of income and resulted in significant resource waste. But thus far they have not frozen the entire sector in an antiquated pattern. To be sure, some policies have had long-run impacts on agriculture—good and bad—and some are now more restrictive than are consistent with societal objectives. Hence there are pressures to change them. This does not argue that policy is an unimportant field of analysis. It is, instead, an argument that the analysis of public choice is more complex than private choice, political exchange more difficult to predict than market exchange.

In the area of public choice, prices and quantities are not available as instruments of analysis. Costs and returns concepts are used less frequently. Consequently some issues are likely to be emphasized more than careful analysis will justify. In the current situation, I would judge the attention given to structure to be relatively misplaced. As another example, I see almost no reason to debate the merits of parity versus cost of production. It is the level of support relative to market prices that counts.

Agricultural economists have a great deal to contribute to the analysis of public policy if they will apply their conventional tools to this unconventional area as objectively and vigorously as they have to market questions. If they fail to do so because of their proximity to producer interests, they will forego an interesting and important area of endeavor that other economists will pursue.

Reconciling Agricultural Pricing, Environmental, Conservation, Energy, and Structural Concerns: Discussion

Allen Grommet

Some day agriculture price and income policy makers may consider the alternating conflicting and complimentary goals of environmental, conservation, energy, and structural concerns, but not in 1981. While I believe that land policy will be the subject of much future debate in agriculture policy forums, that time has not arrived. I do not believe that the quadrennial review of major farm legislation occurring in 1981 will change legislation significantly from the 1977 bill. I suspect the debate will be mostly on loan rates and target prices, with a continuation of the grain reserve rather than addressing the broader context of land policy discussed by Martin.

The comments here are not intended to represent those of the Congress, the House Budget Committee, or its staff on which I work. Instead, these remarks are personal reflections on likely agriculture legislative issues as a student of the policymaking process.

Martin has found the common denominator that could be used to reconcile many of the conflicting issues facing the broadly defined agricultural community. Even in the 1930s, farmers realized that when price and income policies could not be sustained under the Constitution on their own, certain supply-controlling policies under the pseudonym of conservation could be used to obtain the same ends. Politically, the policy issues may evolve in another decade or so where land policy may once again be the central focus of agricultural policy. In order to continue to receive the benefits of price and income policies, farmers may well have to form coalitions with environmental, conservation, energy, and other groups. The common factor that bonds these groups may be policies affecting land. And certainly any policies affecting land will have an effect on farm structure. While I agree with the technical possibilities of reconciling these issues through land policy, I believe there are strong institutional encumbrances stalling this eventuality at the national level.

Allen Grommet is Chief Economist for the Committee on the Budget, U.S. House of Representatives, Washington, D.C.

Interest Group Dynamics

If all of the issues affecting agriculture are going to be reconciled, there must be a constituency interested enough in each issue to push for legislative changes. Currently that constituency does not exist for some of these issues when farm income and prices are discussed. Environmental, conservation, energy (except biomass in the 1977 farm bill), and other interests tend to be "one-interest" interest groups that shy away from omnibus legislation. Most farm organizations as well do not want to compromise income and price policies with other concerns. Without an interest group participating in the agriculture policy debate that is willing to bargain and trade influence on the public decision process in order to obtain concessions from traditional farm groups, the agriculture price and income interests simply will not introduce the additional issues into the debate.

Land policy issues such as conservation, environment, and energy are earnestly debated by such groups as the National Wildlife Federation, the Sierra Club, and others that have never been involved in influencing agriculture legislation. Until these groups are ready to show their concern about how these issues should be considered within the context of farm income and price debates, no reconciliation will occur. In fact, at the present time these environmental groups are not even recognized as legitimate participants in the farm income and price debate. Legitimacy could be achieved in time with direct testimony to the agriculture committees and overtures not only

to the Department of the Interior but also to the Department of Agriculture. Further legitimacy could be obtained by developing a block of congressmen and senators who are willing to put their names on the line in the agriculture income and price debate as being equally if not more concerned about environmental and conservation matters than about farm income and prices. Until that happens, policy making in the Congress will not force a reconciliation of these issues.

Lack of a Forum for Reconciling Conflicting Land Policy Issues

Not only are there no interest groups working to reconcile these conflicting issues, but the institutional structure of the federal government generally prevents reconciling these issues. Jurisdictions and responsibilities are so split and delineated that they prevent reconciliation of these policy issues until they reach the highest levels of government, and often the differences in the issues are not significant enough when compared to other national issues to warrant the attention of the president, the White House staff, or congressional leadership.

If the Department of Agriculture were going to play a leadership role in reconciling the conflicting issues involving agriculture, they would have to work with a long list of other agencies and departments. For instance, the Environmental Protection Agency plays a leading role in environmental issues affecting farm chemical usage and nonpoint source pollution, such as soil erosion. The Department of Energy plays a lead role in developing fuel and energy alternatives such as gasohol. The Food and Drug Administration is involved in food regulation. Structural problems such as the development of farm coops have been handled by the Department of Justice. International trade issues involve the Departments of Commerce and Treasury as well as the Office of Special Trade Representative and the International Trade Commission. As a consequence of these and other possible examples, it is difficult to see that the many conflicting agricultural issues can be resolved or reconciled even at the cabinet secretary level without involving an "arbitrator" with authority over a number of departments.

If we look at the Congress, similar jurisdictional disputes occur. The Agriculture Committee handles the price and income policy; however, the Science and Technology Committee in the House is the major forum for discussing all research programs including some agriculture research. The International Affairs Committee handles major matters on trade. The Public Works Committee reports bills affecting transportation issues. The Ways and Means Committee handles all the tax legislation that has significant influence on the structure of farming. The Small Business Committee is involved in loan policy affecting the structure of farming and other small businesses. The Labor and Education Committee in the House reports legislation on the human nutrition programs. And if that separation of jurisdiction is not enough, the Appropriations Committee is split into thirteen different appropriations subcommittees where spending authority is further separated.

Even the budget process does not force a reconciliation of these issues in the agricultural sector. The budget forces many trade-offs among competing parts of the economy, but on a much broader base than the agricultural sector. Energy is treated in the context of all energy programs; conservation is treated in the context of other natural resource programs. The agricultural function in the budget deals only with the farm support programs, service, and research programs. The programs in the Department of Agriculture fall into some seven different functions of the nineteen in the federal budget.

More Research Needed on Institutional Developments

The biggest problems in reconciling the broad content of agricultural issues (including land policy) are the institutional limitations. Further economic research on these issues is important, but one should not look to the legislative or executive decision process to reconcile the policy differences on these issues any time in the near future.

The piecemeal approach attempting to solve each of these different policy issues, while not necessarily the most efficient method, may still make improvements, but a coherent policy among all of these issues must await further institutional developments.

The Farmer-Owned Reserve: How Is the Experiment Working?: Discussion

W. Scott Steele

The paper written by Meyers and Ryan does a good job reviewing the background and operation of the farmer-owned reserve program. They also have developed a model to analyze the market impact of the reserve. Their results indicate that without the reserve we would have seen lower average prices and higher price variability. Finally, the authors raise a number of relevant issues about operational problems as well as the future prospects for the reserve as a policy instrument.

I would like to elaborate on their paper, giving my impression of how well the reserve has worked and what needs to be done to keep the reserve operating effectively in the interest of both producers and consumers.

The Meyers-Ryan paper correctly points out that raising the storage rate and allowing immediate entry of 1976 and 1977 crop wheat into the reserve were important factors in increasing the rate of accumulation after a slow start. Nevertheless, producers had substantial incentives to enter the reserve during the accumulation phase. The release level was higher than farm prices during 1977 and 1978. But, with the target price set above the release level for the 1978 and 1979 crops, producers had a reasonable expectation that farm prices would come up to or near the release level. Because the producer had to recover only about 14¢ more than the prevailing farm price (6% interest for the first year of the reserve loan) to break even, the potential benefit of entering the reserve outweighed the cost.

Prices increased during May 1979 and triggered release of the wheat reserve. Removal proceeded in an orderly manner over the release period. This was contrary to the expectations of some who believed farmers would dump reserve grain on the market.

The situation for corn was similar to that of wheat. Farm prices in many areas were below the loan rate. Producers had substantial incentives to enter the reserve during the accumulation phase. The release level was higher than the farm price during 1977 and part of 1978. The producer had to make only 12¢ per bushel more than the prevailing price to break even.

As with wheat, the opportunity for farmers to enter corn immediately into the reserve greatly accelerated the rate of accumulation. In June through August, corn was in release status and, like wheat, removal of the corn reserve took place in an orderly manner.

The initial phase of the wheat and corn reserves went smoothly. The incentives were there to gain the participation of farmers. As I indicated, the key to participation was the relationship between the farm price, the loan rate, and the release level. Farmers had a reasonable expectation that the release level would be achieved. A higher release might have been attractive because the potential gain would have been larger. However, if producers did not have an expectation that the release level would have been achieved over the three-year reserve contract, they may have been reluctant to enter grain in the reserve.

Although the wheat and corn reserves performed effectively, the barley reserve did not. The problem was that the price series that was used to trigger release and call of barley was a national all-barley price series. As a result of higher prices on the West Coast, where less than 10% of the reserve was located, and because of the influence of malting barley, which usually commands a premium over feed barley, the barley reserve was placed in call status beginning 26 June 1979. However, farm prices in most of the Northern Plains, where the reserve was held, never rose above the release level.

Several changes in reserve operating procedures were necessary. Because the release and call levels are based on the barley loan level, and because the barley loan is tied to the

The views expressed do not necessarily reflect those of the U.S. Department of Agriculture.

corn loan on a feed value basis, it did not seem appropriate to use a barley price series that included malting barley. It was decided that a feed barley price series should be used. Second, because the West Coast barley market greatly influenced release and call of the reserve and West Coast producers participated only marginally in the reserve, it seemed appropriate to use a feed barley price series that was related to the location in which the reserve was held.

Changes in the operation of the reserve had been in the planning stages for several months prior to the Soviet suspension. However, in order to deal with the domestic impacts of the suspension, greater incentives were given to farmers to participate in the reserve program. Some adjustments in the reserve no doubt would have been made even without the suspension.

Periodic adjustments in the reserve program are needed so that it remains attractive to producers. Participation in the program is needed if there is to be sufficient grain in reserve to meet shortage situations. The adjustments in the reserve that need to be focused on are the loan rate and the release and call levels.

The loan level is important because that is the "price" the farmer receives for going into the reserve. Unless farmers can be assured of sufficient operating capital to meet their cash flow needs through these loans, they will be reluctant to commit substantial quantities of grain to the reserve. The loan level can be adjusted to make the reserve entry more attractive. In this regard, the administration recently raised wheat and corn loans which, in turn, raised release and call levels. Moreover, it should be noted that Congress is now working on new legislation, which is supported by the administration, to provide authority for a special loan for reserve grain. This special loan would provide for a supplemental payment over and above the general loan and would give a further incentive for program participation. The release and call levels still would be set in relation to the general loan and would be unaffected by this legislation.

As mentioned, the release and call levels are also major determinants for the effectiveness of the reserve. To attract any significant quantity of grain, the release level must be high enough to cover the current price plus any additional costs incurred by the producer from entering the reserve.

Another consideration in setting the release level is the target price. In order to reduce budget exposure, the release level should be set above the target price. Otherwise, the operation of the reserve could force additional outlays for deficiency payments.

Finally, the release and call levels need to be adjusted in order to provide the opportunity for adequate returns to producers in the face of rising costs. If the operation of the reserve does not permit farm prices to cover costs and provide a profit from time to time, then the reserve would be placing the farmer in a disadvantageous economic situation. During the current year, we have seen costs of production increase dramatically. The July adjustments in loan rates and release and call levels will provide greater flexibility for market prices to match these cost of production increases. Further adjustments in the reserve for the 1981 crops are now under review. In making adjustments in reserve operating rules to compensate for increasing production costs, Meyers and Ryan remind us of the potential problems of using the reserve to support prices above world market equilibrium levels.

If adjustments in release and call levels are made periodically, keeping in mind the considerations I have mentioned, then the reserve should be viable over the long term. Farmers should continue to participate in the reserve and by doing so, will ensure themselves higher returns as well as provide consumers greater assurance against severe price increases.

Based on our experience so far, we generally can conclude that the economic situation of farmers is better with the reserve than without it. The other side of the coin is the benefit to taxpayers and consumers. They incurred costs as the reserve was accumulated and only benefit when it is released. When the farmer-owned reserve has been in release, we have seen an orderly withdrawal of grain and the tendency for price increases to moderate. However, the reserve has not been tested in a really tight supply situation. That situation may well be on its way, given the current outlook for 1980 U.S. feed grain production. Hopefully, the reserve will meet the test.

Changing Rural Data Needs

Changing Rural Development Data Needs

James T. Bonnen and Glenn L. Nelson

Rural America is changing. It is changing more rapidly and in more fundamental ways now than perhaps it has since farming displaced hunting and fishing. Entirely new questions about the nature of these changes and the future of rural life are being raised. Answers are often difficult to obtain.

We have long paid too little attention to the nonagricultural dimensions of rural society, allocating few research resources and paying inadequate mind to the policy needs of rural society. Farmers and their families now constitute only 13% of the rural population (U.S. Dep. of Commerce). The migration of millions from farming has come to an end, leaving a very different rural society behind—one in which farmers are a minority, and agriculture provides employment for only 10% of the rural work force (Deavers and Brown).

Rural America is now in a rapid transition toward a new and very different society. The tide of migration has turned back toward rural areas, where population is now growing more rapidly than in the cities (Beale, Beale and Fuguitt, Morrison and Wheeler). Rural communities have become so heterogenous in social and economic character that, not only can most no longer be described as just farming communities, but it is often difficult to describe them accurately at all from the current data base. Of the approximately 39,000 local units of government in the United States today, more than half have populations of 1,000 or less, 70% have less than 2,500 (U.S. Dep. of Commerce). These communities have limited capacity to develop their own data bases. Census of population and housing data on the social and economic conditions of rural people and their communities, while generally the best we have, are available only once every decade and for these smaller communities are neither very comprehensive nor reliable.

Because the nature of rural society is changing rapidly and the rural population now appears to be the fastest growing sector of the U.S. population, the lack of ability to understand that change and to provide coherent policy direction can have costly consequences. Rural America is not just a residual left behind by the urbanization and industrialization of the United States. It is more than a fourth of all Americans, and it is a diverse and growing sector of the economy whose problems are an important part of the decentralization of national economic activity and population now taking place. Effective public and private policy requires an appropriate rural data base. But there is no consensus on what constitutes such a data base.

It is the conclusion of this paper that the inadequacies of the rural data base are part of a complex problem of circular causation. There is widespread agreement that the data base is deficient but little consensus on what constitutes the most important deficiencies. The question of what needs to be done does not elicit a coherent answer.

The lack of coherence that characterizes the current data base is due to a lack of coherence in rural development policy itself. The specification of data needs and design always arise out of use. This policy area has long been characterized by a slowly growing collection of specific programs. Collectively, however, they do not amount to a coherent policy and do not imply an integrated view of present

---

rural problems or of the future of rural society. Why?

Short-run explanations tend to focus on the fact that the programs serve different clientele and are managed by a large number of different agencies, accountable through various lines of authority, scattered over several cabinet departments.[1] In the long run, these obstacles would not be insurmountable if we, as a society, had an intellectually coherent, widely accepted, prescriptive vision of the future of rural society, and some sense of the obstacles to that vision. In fact we do not.

Our inability to develop any clear prescriptive vision of that future arises from two primary sources. One is a long-time failure to recognize and resolve the broad value conflicts implicit in the different views various groups hold about development issues: the growth of government services, tax equity, land and water development and use, centralization versus local self-determination in governmental services and organization, and others.

The other source of this failure to evolve a coherent vision of the future arises from the deficiencies of the data base itself. The extensive nature of the changes in rural society and the speed with which many of these changes have come have left us with a poor descriptive and conceptual understanding of the current state of rural society. In fact, we still cannot define clearly what the concept "rural development" means (Daft 1978). Thus, the circularity of the problem arises ultimately out of the interdependence in policy decision between positive and normative knowledge as well as the inherent epistemological dependence of conceptual (deductive) knowledge on empiric (inductive), and vice versa (Bonnen 1975, 1977).

Even if one sets out only to describe the deficiencies in the data base and their origins, one is led eventually into this circular train of causation. The problems of the rural data base are most clearly understood when seen as an information system failure. Thus, we will devote our efforts here to an evaluation of rural development policy as an evolving information system. A data base can only be defined and fully understood as part of a larger decision system.

[1] Bryant has an excellent analysis of the lack of coherence expressed in terms of the fragmentation of the demand for rural economic and social statistics and the dominance of the supply side by a few federal agencies with little bureaucratic interest in rural people.

In this paper we shall briefly examine the historical evolution of development policy and follow it with an assessment of the current state of rural society. Then, we will evaluate the implications of all this for rural development data needs. Finally, we report briefly on a National Academy of Sciences panel which is addressing the problems of "Statistics for Rural Development Policy."

The Evolution of Rural Development Policy

American citizens have been guided in their lives by a system of values which has remained quite stable. John Brewster identified several closely related sets of values in an examination of nineteenth century America (see especially pp. 14–28 and 60–61); this configuration of values has remained a dominant influence in rural life. Democratic values include the ideals of equality, self-determination, and representative democracy. Work values attest to the worth of work, the importance of equal opportunity in preparing for and finding work (distributive justice), and the commutative justice of a fair return. Enterprise values include the beliefs that success in private enterpreneurship is a proper test of a person's worth to society and that the competitive striving of entrepreneurs yields the most good for all, including sufficient jobs for all who wish to work.

Facts, i.e., our understanding of reality, have been considerably more volatile than values. Individuals and the institutions of society are continually buffeted by new situations, especially changes in technology and knowledge, that render obsolete previous beliefs about the facts of their situation. In turn, problem definitions, which reflect the difference between "what is" (beliefs about facts and values) and "what should be" (prescriptive beliefs), will change, with public policies then modified to address better the redefined problems.

Over long periods of time one observes changes, not only in beliefs about facts, but in values and prescriptive beliefs. These changes are interactive or dynamic. The rest of this section summarizes the results of a historical analysis of rural development policy. Shifts over time in policy are interpreted in terms of perceived imbalances between changing beliefs about "what is" and "what ought to be" in rural life. It is this perception of imbalance

which powers and limits what is possible in the policy process.

Cochrane's recent volume on the economic history of U.S. agriculture provides an especially useful historical starting point for this analysis. We are also dependent on the rural development literature including that from rural sociology. The interpretation and framework are entirely the responsibility of the authors. We started in the mid-nineteenth century and examined the changing perceptions of rural society, its values, problems, and related policy responses. Our conclusions are necessarily composed of generalizations about quite complex matters.

In the mid-nineteenth century, the traditional value system of rural America outlined above provided clear, rather stable role images at work and in the family and a strong faith in nature and natural processes. Rural communities were generally isolated, self-sufficient farming and mining or lumbering communities which, compared to today, were each relatively homogenous in values. The frontier was perceived as offering an equal opportunity to all, though hard work was expected. Enterprise beliefs were strongly held and viewed as an important cause of American success. The appropriate role for government was limited to the provision of services which people needed to become established and to prosper as proprietors.

Up until the 1950s, agricultural policy and rural policy were viewed as synonymous. National policy responses designed primarily to affect rural welfare focused on farmers as proprietors. Such policy actions in the nineteenth century facilitated farmer access to land through homestead legislation, subsidized development of a transportation network to deliver inputs and market outputs, and attempted to assure equal social and economic opportunity for farmers through land grants for public education. These policy actions supported greater attainment of democratic, work, and enterprise values with little need for trade-offs between values. Twentieth century rural policy can be characterized primarily as responses to perceived market failure; the earliest legislation on farm credit passed in 1916, land reclamation and irrigation in 1902, soil conservation in 1933, and commodity price supports in 1929 and 1933. Though focused on consumer as well as farmer welfare, growing economic concentration and monopoly led to the first antitrust legislation in 1890; abuses by food marketing firms resulted in regulatory legislation (1906 and 1921) setting standards for food safety and controling meat packing and stockyard practices.

Thus, the twentieth century saw a very different pattern in rural value attainment and policy. Technological, social, and economic change created market failures and concentrations of power which impaired democratic values of equality and self-determination, as well as the equal economic opportunity and fair return values of the work ethic. The Great Depression of the 1930s was a watershed in social policy, which shattered the belief that a freely competitive system would produce prosperity and jobs for all who wished to work. The policy response was to trade a substantial impairment in enterprise freedom for greater attainment of democratic and work values.

Following World War II, the perception of rural society began to change. The exodus from agriculture reached unprecedented rates in the 1950s and 1960s as a major technological transformation occurred. Slower national economic growth over the last half of the 1950s led to a back-up of underemployed labor in rural areas. Rural incomes lagged significantly behind urban, and again rural people faced a growing mismatch between actual conditions and their work values. While the major policy response was still in terms of farm programs, for the first time a growing realization that agriculture and rural could no longer be regarded as synonymous led to new policy initiatives.

The community self-help programs of the 1950s and early 1960s reflect an uneasy tension among values related to equity, enterprise freedom, and community self-determination. The Rural Development Program of 1955, the expansion of Farmers Home Administration programs to rural housing, water, and sewer needs, and the Rural Areas Development program of 1961 were intended to aid rural communities in organizing to solve local problems. In actual fact, the programs were modest and had little impact. They did recognize, however, for the first time that revitalizing rural areas required more than just farm programs.

In the 1960s and 1970s, small business loans, housing, public facilities, and development planning programs for small communities were created in several agencies outside the Department of Agriculture (USDA).

The Rural Development Act of 1972 brought together in one place, and expanded substantially the authorizations for, many rural development programs. However, the emphasis remained, as it has since the 1950s, on programs not policy, on community self-determination, and on the welfare of places not people (Daft 1972). The Carter administration announced its Small Community and Rural Development Policy in late 1979. This involves no significant shifts in programs or value trade-offs.

But the larger society was in ferment. The mid-1960s through the 1970s saw an explosion of government activity in response to increasing dissatisfaction with the attainment of democratic and equal opportunity (distributive justice) values. The rights of minorities to participate fully in the nation's political, social, and economic life were strengthened. Consumer and worker health and safety as well as environmental protection became major issues. Many of these policy initiatives further restricted enterprise freedom in order to enhance the democratic value of controling one's own destiny and the work values of equal opportunity and fair play. While new programs were directed specifically at depressed rural areas, this period is better characterized as one in which rural areas were swept along in a new wave of national policies, than as a period of new rural policy creation.

Current State of Rural Society

Rural institutions have evolved through the interplay of new factual knowledge and shifting priorities among values. This is a continuing process. Technological and social changes are occurring at a more rapid pace in nonmetropolitan America than perhaps any time in history. Changes in "what is" show signs of outpacing the capacity of institutions to establish and achieve society's beliefs about "what should be." We sketch below the current state of some of the major dimensions of rural society.

While the enthusiasm for science and technology has been dampened by nuclear accidents and chemical residues in the natural environment, they remain powerful forces for change. Since World War II, technological innovations in transportation and communication have made possible a decentralization of production and distribution with centralized control. This has permitted the steady growth of manufacturing and service employment in rural areas over the last three decades. Even the headquarters of some firms are now locating in rural environs that have convenient access to a major airport. Thus, the centralization of control no longer necessitates the kind of spatial concentration of economic activity which characterized the first hundred and fifty years of the industrial revolution and powered the growth of metropolitan areas. We have reached the end of a long era of increasing population concentration.

The return migration and a rural population now growing more rapidly than metropolitan are the product of extremely complex forces which we have only begun to understand. The slow decentralization of economic activity and employment is only part of it. Extensive interstate highways now allow more people to commute to work over longer distances. The earlier migration to the city for jobs is now leading to a return for retirement. Second homes for recreation become retirement homes. Development of new energy sources has created boom towns and large rural electrical power generation sites in Western coal areas. Americans have long had a preference for rural residence (Zuiches and Fuguitt). Only in the last few decades have economic opportunities and higher levels of living enabled them to act on their preferences for rural amenities.

Urban mass culture began to influence rural values, self-perceptions, and world view as soon as the isolation of rural life started dissolving in the revolution of transportation and communication technologies. The growing involvement of rural people in industrial and urban vocations, in higher levels of education, in use of the mass media, and in greater spatial mobility leads to a general convergence of rural values and beliefs with those of urban life. Though many differences remain and even grow, rural and urban life are slowly moving toward each other in many beliefs, in material levels and standards of living, even in desired amenities (Larson). This convergence likely will be accelerated by the return migrations.

We long ago reached the point where "there is no separately manipulatable rural society" (Daft 1972, p. 4). The integration of local rural markets and social organization into the evolving urban social order makes it impossible to construct a rural development policy with a

unique geographic basis distinct from urban. Too many economic and social structures and problems are common, and most are regional or national in scope.

On the other hand, there are also great differences between rural and larger urban communities. Unique to rural society are the diseconomies arising from the greater space over which all organizations and functions must operate and the very different mix of resources, enterprises, vocations, and amenities which still characterize rural communities. So, some problems are quite different. Policy and legislation addressed to such diversity will itself be inherently diverse. An omnibus rural development policy is an impossibility. In some cases, the unique aspects of rural communities and their needs can be recognized in designing national policies. In others the problems may be so uniquely rural, separate programs and policy are needed. Even these are likely to be scattered over several executive departments and congressional committees.

As rural life has been integrated into an urban society, its economy and vocations have grown far more diverse. Self-sufficiency, isolation, and local organization have slowly given way to regional specialization and to a system of mostly national level economic and social institutions. This newer, evolving social order has increased productivity. But its specialized institutions have also increased the dependence of individuals, organizations, and communities one on another and reduced the local community's capacity for problem solving. Resolving local community problems requires cooperation between and integration of the activities of many of these same specialized, nationally directed systems. This is difficult because they are often more inclined to bureaucratic warfare than to cooperation. This change leads toward a concentration of economic and social power which simultaneously undermines enterprise freedom as well as the real achievement of democratic values.

As society grows complex, technical, and bureaucratic, the individual becomes dependent on people, organizations, and forces he or she does not know or understand. The sense of self becomes depersonalized and problems with life are less frequently perceived as arising out of one's own personal limitations and are attributed to deficiencies of the society. This has major implications for the way norms and reality are interpreted and for what is seen as an appropriate policy response to a problem.

Rural society is more heterogenous and pluralistic. All the variants of nineteenth century rural as well as today's urban lifestyles and beliefs now coexist and contend through rural life. Pluralism undermines absolute value commitments of traditional societies and leads to relative standards. It weakens the individual's faith in any particular system of values and shifts one's perception of what is significant from the institutions of society, i.e., from one's environment to one's own unique subjective experience (Coughenour and Busch). Thus, as beliefs about values and objective reality share less of a common basis in experience, they become less stable and more fragmented. This undermines the social basis for policy and assures that future rural policy will be less stable and more contentious, from local levels to national.

The social and economic changes described earlier have transformed the structure and the role of government. Every level of government has acquired new functions, most regulatory in nature, and public subventions and services have grown immensely. Dependence has grown proportionately. In 1977, almost a fourth of state government receipts were federal monies, and almost 40% of local government receipts were state and federal monies (Dep. of Commerce, p. 289).

However, federalism with all its growth is in disarray, with no clear division of labor and an uncoordinated mixture of programs in which accountability and even purpose are often hopelessly confused. Responsibility for this chaos recently was laid at the door of Congress by the Advisory Commission on Intergovernmental Relations. The states, through the National Governors Conference and the National Conference of State Legislatures, are pressing hard for reform (*New York Times*).

While the authority of states has been progressively undermined by the federal government for decades, the states now are starting to assert themselves with some vigor. The other unit of government that appears to be in resurgence is that of the county. While the variation in nonmetropolitan America is extreme, those counties sharing in growth often exhibit a fiscal strength and management sophistication which local municipalities cannot match.

The ability of local government to deal with the current chaos in federal relations is quite

limited. They are frustrated and feel trapped between a rising tide of complex problems, their limited expertise and capacity, and a chaotic set of state and federal bureaucracies which intrude unilaterally and are quite uncoordinated and insensitive to local problems.

Public policy is the product of effective political power (Daft 1972, p. 4). The nonmetropolitan or rural counties, townships, and cities of the United States are not now effectively organized and represented in most states or at the national level. Farmers are organized but now constitute only a small minority of the rural population, and their economic interests are quite different. Until the rural units of government form an effective political coalition, there will be a political vacuum in rural America. Growing economic and social vitality and the return migration eventually should make this vacuum intolerable at the same time that it creates a potential political base of some consequence. But such does not now exist.

Implications for Rural Development Data Needs

The social value of rural development statistics is growing rapidly and will continue to do so for the forseeable future. Rapid change is introducing great uncertainty about matters of growing social significance—the future of rural society and a decentralizing social order. This, in turn, greatly increases the value of information necessary to deal with that uncertainty. We are entering a new era, the full implications of which are yet to be grasped. Until we understand it better, this transformation initially requires a major intellectual and research investment. The future contains many new elements and potential benefits and dangers. Our concern should be (*a*) that rural people understand what is happening to them, and (*b*) that intelligent policy direction be given to avoiding the dangers and to pursuing those potential opportunities that are responsive to the goals of local communities and of the society.

The growing uncertainty rural America faces is produced by important issues of increasing concern. One is the energy crisis. What impact will higher energy costs have on the return migration and the decentralization of economic activity which lies behind it? We will make many important public and private decisions in accommodating higher energy prices.

If the return flow of population and the rate of economic growth continue in nonmetropolitan America, clashes over land use and environmental issues can only grow more intense and more important. Similarly, the conflict over growth versus no growth, as well as the equity of various local community tax and expenditure policies under different growth philosophies, will grow.

The growth in government has unleashed a multitude of conflicts over modern federalism. What is the appropriate role and scope of government at federal, state, and local levels? How the other issues above are resolved will condition what roles and functions are finally focused at different levels in the federal system. Pressure to build greater capacity into local units of government will expand (Doherty).

As well as the accelerating intensity of specific growth issues, increasing complexity produces greater uncertainty and expands the intrinsic need for and value of information. The sources of this growing complexity include the fact that the distinction of rural versus urban is no longer a useful organizing principle. It is now too simple a concept to capture the varieties and conditions of community that exist today. Another complicating force is the greater centralized control of economic and social institutions now accompanied by decentralized activity. This implies a more complex capacity for coordination which not just the involved organizations but various information systems must sustain as well.

The increased heterogeneity and pluralism of rural society create a future with many more options than existed in the past. If these proliferating alternatives are not examined carefully at all levels in society, missed opportunities will grow and the probability of satisfactory outcomes will be reduced.

Fragmentation and increased relativism of values lead to a subjective self-image and world view. Consequently, an objective statistical base becomes an even more critical resource but also one more vulnerable to being politicized by subjectivity. Objective data do not necessarily add to stability without some consensus of related values. Achieving consensus where values are highly fragmented suggests the need for open public policy institutions and wide participation in reaching a

legitimate value consensus or at least a compromise that minimizes the political costs.

Both what is as well as what ought to be are at hazard in the decisions that will be made. The conflicts over values as well as fact need to be consciously addressed. The return migration and the imposition today of national trends on small communities are sure to fuel further conflict between enterprise values, equity, and democratic values. Federal government programs and regulation are already generating a severe conflict with the democratic value of self-determination expressed at the local level of government.

An adequate data base becomes more important as uncertainty is compounded by rapid rates of change and increasing complexity. Statistics cast many long and enduring shadows in policy and in the lives of people. The absence of appropriate data often casts even longer and more enduring shadows.

What kind of strategy for data development does this imply? To us, it suggests the necessity of an experimental or developmental strategy capable of discovering problem definition, decision information needs, the proper related concepts and analytical techniques, and the empirical needs for those decision purposes. In such a mode of inquiry there is no suggestion that one might succeed by addressing only one part of the system or that the entire information system could be built in a year or, in this case, even a decade. In reality, an information system is a process that never ends. The specifications for a data base develop out of the knowledge gained as the inquiry process, which supports a set of decisions, evolves. The difference is only the level of knowledge from which one starts and the rate at which that knowledge is made obsolete by change (Bonnen 1975).

We need also to realize that the idea of a singular coherent data base for rural development policy is a chimera—a Holy Grail never to be discovered. It cannot exist because there is not, and never is likely to be, a single comprehensive rural development policy. We can, however, address the data base problem in the context of specific policy decision areas, such as health, housing, land use, etc., where there is some necessary presumption, as well as possibility, of coherence in decision. Major problems arise, of course, when a decision involves trade-offs between these specific policy areas.

What can one say about the basic statistical problem? All statistics are labor-intensive, especially the collection process, and thus they have become more expensive in the United States. As one goes from large cities to the smallest, data of the same detail and accuracy require higher sampling rates and are even more expensive. Rural societal decisions increasingly require data in greater social and economic detail than are now available. These data also need now to be updated more often than they are. For many uses they need to be comparable to existing economic and social statistics for the United States. Thus the dilemma. Given the cost of data, how do we satisfy rural data needs without bankrupting U.S. state and local governments?

The value of data and their design criteria arises out of the uses of that data. The heterogenous nature of rural development policy and its information base requires extensive integration and coordination of decisions and information between many organizations and bureaucracies at every level of government. This implies a coherence in our federal structure that does not now exist. In fact, it is resisted stoutly by the public bureaucratic and private economic interests involved. Incoherence of the structure of decision ensures an incoherent data base—even for limited policy areas.

As a practical matter, what do we need to do to improve rural data? The first is experimental and research work. We need to understand rural society and the forces that are so rapidly changing it. We need to develop and improve the concepts, analysis, and measurement that inform that knowledge. Positive as well as normative knowledge is required for policy prescription. We must examine the implications of the alternative factual and value choices that lie before us. All levels of government should be experimenting, in search of better problem identification and means of solution. Statisticians need to work on statistical strategies and methods that can substitute for the more expensive conventional survey and census methods.

Federal and state levels of government clearly have major responsibilities to local government for the development of an adequate local data base. Many local data needs arise out of federal and state program requirements. Regulations and programs that create unnecessary problems and data de-

mands need to be revised. Federal, state, and local governments must cooperate in coordinating data needs among each other if an adequate common data base is ever to be developed without waste and duplication (Bonnen et al., 1980).

Conclusion

This paper has attempted to demonstrate several closely related matters. Rural development data deficiencies, with their circularity of causation, can be most clearly understood as information system failures. Second, what constitutes an improvement in specific data is completely conditioned by the purposes for which they are used and thus by the value structures and objective conditions of rural life that generate specific policy needs. Finally, rural development policy is, and will continue to be, a complex web of federal, state, and local activities, policies, and institutions, which to have coherence and a minimally adequate common set of data bases must, in some degree, be a coordinated system.

We have tried to define the nature of our persistent inability to specify "the" rural development data base and have put our emphasis on what tends frequently to be missed, the institutional information system and preconditions from which specific and coherent data needs are derived. This will disappoint those looking for specification of concrete data sets. That would require another article and, even then, would disappoint those seeking a statistical Holy Grail.

The authors' current perceptions of rural data problems arise from their participation in the Academy of Sciences Panel on "Statistics for Rural Development Policy." Academy regulations prohibit public discussion of panel recommendations before Academy publication. The Panel report undoubtedly will provide a more concrete specification of data needs and statistical strategies. That report should be available by early 1981. Because the Panel faces the same intellectual and institutional problems addressed by this paper, it is likely that their recommendations will focus on needed institutional change as well as specific data problems. We believe the Panel report, *Rural America in Passage: Statistics for Policy*, will be both useful and challenging.

Some Concepts for Measuring the Economic Value of Rural Data

J. Bruce Bullock

Economists somewhat belatedly have begun to recognize and to understand the role of information in economic activity. The topic has received attention only since Stigler's seminal article on the economics of information was published in 1961. We have ignored the role of information in economic activity largely as a result of our almost exclusive use of theories and models based on the assumption of perfect information. Consequently, we have tended to assume away problems and complications caused by less-than-perfect information rather than to develop formal theories and/or models to deal with these issues.

Once we accept the fact that perfect information does not exist, one is hard pressed to arrive at measures by which to evaluate the performance and efficiency of various types of economic activity (Pasour and Bullock). Moreover, we begin to recognize that certain types of less-than-perfect information have economic value both to individual decision makers and to the public at large.

We have long realized and accepted the potentially positive contribution of publicly financed systems for the collection and distribution of various types of agricultural data. The usefulness and value of these data (information) systems have been taken more or less for granted. However, the increased public scrutiny of budget expenditures and the increased emphasis on program planning and budgeting as a tool of budget management has heightened our interest in determining the economic value of these systems and of proposed changes in the systems.

Our interest in public information systems has also been stimulated by other developments. The increase in the number of "thin" markets for agricultural products has raised numerous questions about the adequacy of our current price-reporting system. The continued trend toward fewer and larger farms and food-processing firms raises questions about the connection between industry structure and the nature of public information systems. These concerns suggest that the value of public data systems may be to monitor economic performance as well as to provide information for individual decision makers.

The purpose of this paper is to examine the current state of theoretical and methodological approaches to valuing information systems and to identify some of the problems and issues that confront efforts to determine the economic value of information systems.

Current Status

Eisgruber provided an accurate status report on the state of economic research relating to the value of information systems. "Neither theory nor methodology exist to address adequately the economics of information, and, until recently, little effort was made to overcome this deficiency . . . (p. 901). Later, he says, "the public as well as the private sectors spend considerable amounts of resources on the development and maintenance of information systems. Yet, as economists, we have, to date, provided little by way of assessing the effectiveness of these information systems" (p. 904).

Although a sizable body of literature dealing with the economics of information has developed in recent years, we have yet to develop an adequate theoretical or methodological framework for valuing information. A large

This paper is in part a product of the AAEA Taskforce on the Value of Statistical Information. Taskforce members were Richard Shumway, Jim Olson, Willis Peterson, Tom Miller, and the author. The paper draws heavily on discussions of the Taskforce and the interim report of the Taskforce. However, other members of the Taskforce should not be held accountable for errors or other shortcomings of this paper.

The helpful comments of Darryl Ray and Boubaker Thabet are also recognized.

portion of the existing literature on the economics of information deals with the search for, and the use of, information by individual decision makers. Questions about the value of various types of public information systems have received less attention.

One might argue that the substantial theoretical contributions of Stigler, Arrow, and others provide an adequate theoretical basis for the economics of information. However, the theoretical developments to date do not include an analytical framework that enables us to translate this theory into meaningful empirical analysis. It is one thing to recognize that information is an economic good and should be used in amounts that equate marginal benefits with marginal costs. It is something quite different to quantify and measure empirically the marginal benefits and costs of a particular type of information. It is these analytical frameworks that are particularly lacking. However, the theoretical foundations on which to develop the analytical frameworks are far from complete.

As we move toward the development of this theory and methodology, there are several questions that will have to be answered. For example: What is information? How is it to be measured? What constitutes an improvement or an increase in information? Tomek's recent article dealing with the role of information in thin markets is an interesting approach to developing an empirical estimation process to deal with these questions.

Value of Information System to Nonmarket Users

Changes in government programs and policies can create new and added value for information. Moreover, the existence of these programs can perhaps place a premium on accuracy of data that exceeds the accuracy premium generated by market users. For example, consider the current price support program of deficiency payments equal to the difference between the target price and the annual average price received by farmers. For a six billion bushel corn crop, an error of only one cent per bushel in measuring the market average price of corn translates into a $60 million difference to corn producers, or to the U.S. treasury, if payments are triggered. The growing number of programs that depend on public data series such as the census and various USDA reports for the allocation of public funds will add to the pressures for accuracy. For example, witness the current discussion about the undercounting of populations in numerous cities.

One of the more important questions about the value of statistical information systems deals with the decisions of administrators of public information systems. Program administrators continuously are caught between the demand by users for more and better information and the pressures of costs that increase more rapidly than budgets. What is the decision framework that should be used to make decisions about changes in the public information systems?

What kind of information about the value of information is needed to make decisions about changes in these systems that are in the public interest? Can public information programs be managed effectively without estimates of information value? A dialogue between researchers and the program administrators is needed to answer these questions, if we are to contribute to this management process. "It is not enough to develop a methodology for estimating the value of information—the value estimates must actually be useful to Government managers in making decisions about information systems" (Miller, p. 5).

As well as determining the economic value of public information systems, there are two additional types of economic analysis that perhaps should be useful to these decision makers. First, there is project evaluation aimed at identifying who is using the information and how they are using it, as well as examination of the information gathering process itself. Moulton, Levinson, and Thomas concluded that "while we find it feasible to measure some benefits derived from Market News Service, we are not sure this is the direction in which to move. Our observations and analysis suggest that efforts might be directed better toward improved organizational efficiency and study of market changes influencing MNS services" (p. 66).

The second type of analysis is impact analysis. Studies like the one by Pearson and Houck are examples of efforts to provide useful information about the impact on price movements of various types of reports. Studies of this type provide answers to some of the critical questions (accusations) raised by individuals concerned about the impacts of government reports.

Value of Information to Market Users

We have numerous theoretical and methodological voids to fill in the process of determining the value of information in the market place. We simply do not know enough about the rôle that various types and qualities of information play in the effective operations of markets. Information undoubtedly plays an important role in the process of price determination, in product price variation over time and space, and consequently, in determining the efficiency of markets. But just what is the role of information in each of these areas? How would a 10% increase or decrease in information impact the effectiveness of these markets, and what would be the value (cost) of this change in information?

We have many unanswered questions about the role and, hence, the value of information in the market place. For example: How much and what type of information is required for a market to perform effectively its price discovery functions? There is widespread concern that the decentralization of markets has led to an inadequate amount of information in many markets. However, until we develop answers to the above questions, our capacity to report prices exceeds our capacity to interpret what the data mean within the context of performance evaluation. Moreover, we have little basis for suggesting changes in the reporting systems. Ward has shown that our existing procedures of interpretation often raise more questions than they answer about the performance of existing price discovery systems.

The availability of public information systems also may impact the structure of the agricultural production and processing sector (Riemenschneider). This relationship further complicates efforts to determine the value of information systems. Even if we can establish a cause-and-effect relationship between the existence of public information systems and industry structure, economic theory provides little operational methodology for estimating the value (or cost) of structural change.

The income distribution aspects of public information systems cannot be overlooked in our attempts to define the value of public information systems. There appears to be a widespread feeling among producers that information about their current and anticipated production levels results in a transfer of wealth from producers to processing firms and consumers. In some instances, producers suggest that the way to beat the "system" is to lie about their actual and planned production. Is this true? Under what conditions, if any, does the release of production estimates and producer's production intentions work to the detriment of producers, either as a group or individually? Is it in the producer's interest to report falsely current and/or planned production levels? If so, is it in their interest to inflate or deflate actual production numbers? Until we can answer questions like these, the agricultural sector may be quite skeptical of any estimates of the economic value of these data systems which we might develop.

Some Theoretical Considerations

Conventional wisdom holds that the value of information increases as its accuracy increases. This conclusion is intuitively appealing and is supported by the conclusions drawn from the Hayami and Peterson theoretical framework of the value of forecast information. Most, if not all, efforts to estimate the value of forecast information have assumed that the value of this information increases continuously with increases in forecast accuracy. However, this bit of conventional wisdom is not always true. Unfortunately, the Hayami-Peterson theoretical framework is incomplete and does not correctly identify the social cost of forecast errors. Because the incorrectness of the conclusions drawn from the Hayami-Peterson model have apparently not been widely recognized, the problem with their model is discussed below.

The Hayami-Peterson inventory adjustment model is illustrated in figure 1. "We assume in this case that production response to a price change can be approximated as being perfectly inelastic during the production period, as denoted by the supply curve *SS*. The market demand schedule [in both time periods] for the commodity is denoted by *DD*" (Hayami-Peterson, p. 121).

Note that Hayami-Peterson have failed to specify the current level of inventory holdings. Furthermore, they neglect to define how inventory holders make decisions about how much inventory should be held from one time period to the next. (Bradford and Kelegian noted this problem with the H-P model, but did not explore its implications.)

Hayami-Peterson continue the development of their model as follows. "Suppose the statis-

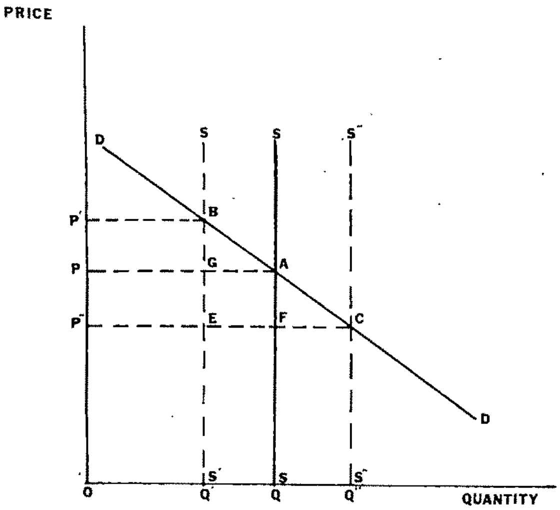

Figure 1. Hayami-Peterson inventory adjustment model

tical reporting agency estimates the current period production as OQ' as opposed to the actual or 'true' production OQ. Inventory holders, in forming price expectations for the coming period, expect the average price to equal OP'. In other words, they would expect the future price to be higher by PP' than would be the case had no error been involved in the production estimate. Consequently, inventory holders find it profitable to decrease their rate of inventory depletion for the remainder of the year, until current price has risen by PP'. Consumption then would contract to OQ', or by an amount $Q'Q$. In turn, the inventory carry over into the next production period would be increased by the same amount, $Q'Q$. As a consequence, the reduction in consumption during the current period would reduce consumer welfare by the area $ABQ'Q$" (p. 121).

There is not enough information in the Hayami-Peterson model to draw these conclusions. Inventory decisions require information about current stock levels and anticipated production in the coming period. Neither of the datum is present in the Hayami-Peterson model. If inventory holders have existing stocks at the beginning of the current period, they will find it profitable to decrease their rate of inventory depletion for the remainder of the year until current price has risen by PP' only if they have reason to believe that production in the coming period will be even less than OQ' by enough so that all inventories can be liquidated in the incoming year at a price of OP' (given the assumption of zero storage cost and a two-time period model). In the Hayami-Peterson model, carryover from the current period (current period production minus current consumption) is then consumed in the coming period along with production in the second period—there are no other inventories being held.

The Hayami-Peterson inventory adjustment model thus does not depict the normal inventory adjustment process of a market. Consequently, the area identified as social costs of forecast errors and the formula for measuring this area do not measure what they are intended to measure.

When an appropriate inventory decision framework is incorporated into the inventory adjustment model, the social cost of forecast errors can be illustrated with the supply and demand for storage services. A quite different set of conclusions is derived.

The social cost of forecast errors depends on whether production is under-forecast or over-forecast. Figure 2 illustrates the social costs generated by an over-forecast of forthcoming supplies. DD' is the demand for storage from the current period to be held into the coming period with perfect information about next period's production and the current level of stocks. DD' is defined by subtracting the excess supply curve for the current period from the excess demand curve for the next period and reflects the marginal social value of

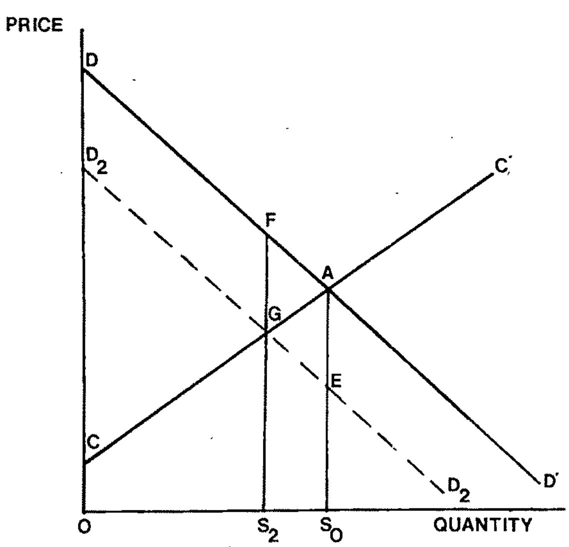

Figure 2. Social costs of forecast errors due to overestimation of production in the inventory adjustment model

alternative levels of storage (Bressler and King, p. 206–9). CC' is the cost of alternative levels of storage. With perfect information, S_0 units will be held in inventory from the current period into the coming period.

The effect of an over-forecast of next period production is to shift the demand for storage to the left to D_2D_2 and to generate S_2 level of storage and hence to generate social costs of AGF.

There is an upper limit of ACD on the social costs associated with over-forecast errors since negative inventory levels cannot be carried from the current period into the coming period. Thus, once the forecast error is large enough to shift the demand curve for storage to the point where it intersects the price axis at point C, then larger over-forecast errors will create no additional social costs. Moreover, in those cases where DD and CC intersect at low levels of storage, the social cost of any under-forecast will be quite small compared with the same degree of under-forecast in a situation where large quantities of inventories would be carried forward under perfect information.

We can conclude from these models that not all forecast errors generate social costs. In many cases, the magnitude of the social cost of an erroneous forecast is independent of the magnitude of the forecast error beyond some minimum level of error. The social cost of a given forecast error is unique to the set of supply and demand conditions existing at the time of the forecast. Therefore, it is not possible to state categorically that an X-percent forecast error will generate Y dollars of social costs. In general, the social cost of an X-percent over-forecast is not symmetrical with the social cost of an X-percent under-forecast. Consequently, the benefits to improvements of USDA forecasts depend on how the frequency distribution of forecast errors is changed (Bullock). This set of conclusions is not very encouraging for those looking for a simple formula to value information generated by forecasts.

Hayami and Peterson also developed a formula for valuing forecast errors for commodities where producers can alter output in response to the USDA report. This model is referred to as the production adjustment model. Their formula expresses the social cost of these errors as a continuous function of the average percent error and the elasticities of supply and demand for the product. Unfortunately, that is true only under special circumstances. In general, there is a discontinuous relationship between social cost and the magnitude of forecast error when producers can alter output in response to the forecast.

The conclusions about the social cost of forecast errors that can be drawn from an appropriately constructed production adjustment model are much the same as those drawn from the inventory adjustment model. That is, not all forecast errors generate social costs. In fact, there are many situations where even erroneous forecasts generate positive social value when producers alter output in response to the forecast. The magnitude of social costs (or benefits, as the case may be) are often independent of the magnitude of the forecast error over a wide range of forecast errors (Bullock).

The problem of determining the value of public data systems is considerably more complex than conventional wisdom suggests. Some type of stochastic simulation process similar to that used by Marquis and Ray may be required to estimate the economic value of these systems. The potential for this approach needs further investigation.

There are several dimensions of information—accuracy, timeliness, reliability, availability, continuity, and perhaps others. Which of these dimensions causes information to have value? Do these dimensions always have the same relative value? An adequate theory defining the value of information will have to deal with the nature of the iso-value line between alternative combinations of these characteristics. The following discussion provides a starting place for developing the conceptual framework for defining the iso-value line between timeliness and forecast accuracy.

A timely report generally is considered to be one that is available at the time the information is required for decision making. This raises the question of whether a report issued one month before the decision date is more timely (and hence presumably more valuable) than the same report issued one week prior to the decision date. Second, is there a trade-off between timeliness and accuracy in terms of the value of alternative reports?

The potential payoff to improving the timeliness of forecasts or reports is illustrated in figure 3. SS represents the preseason supply curve on which producers base their initial production decisions. DD is the harvest time (say July) demand curve for the product (assumed to be known with certainty). Suppose

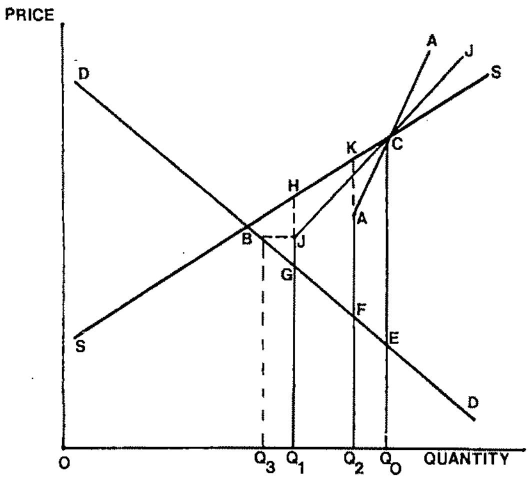

Figure 3. Illustration of potential social value of more timely forecast

that in the absence of information about the magnitude of their combined decisions, producers are gearing up to produce at output level Q_0. If no information is provided to producers about their combined decision prior to harvest time, then output Q_0 will be produced, and the resulting resource misallocation will generate social costs represented by the area *BCE*.

The extent of the response by producers to information about their combined production plans will depend on when the information is released. JJQ_1 represents the supply response if a report is released in January. However, producers would respond to the same information along the curve AAQ_2 if the information were not released until April. This implies that an acceptable alternative use of at least some of the resources exists under some conditions and that the options decrease as the time between the release of the forecast and harvest period shortens.

If an accurate report of current production intentions (i.e., Q_0) is released in January, producers will reduce output to Q_1 and, hence, the social value of the report is the area *GHCE*. However, the same report released in April has social value of *FKCE*. The area *GHKF* then represents the social value of making the information available in January rather than April (social value of timeliness). This is only part of the social value of timeliness. The social value (cost) associated with changes in the output of products to which the resources are shifted is not accounted for in the analysis. Some type of simultaneous multicommodity model will be required to deal with this issue.

There will be an economic value of improved timeliness only if the production decision is reversible to some degree over some time interval. Moreover, the degree of reversibility must decrease as each stage of the decision process passes as reflected by the differing slope and range of possible output response depicted between JJQ_1 and AAQ_2. Therefore, there is a limit to the amount of improved timeliness that will generate social value. When the report is issued to be timely for the *SS* stage of the decision process, no further gains in social value will be generated by making the report available at an earlier date.

The above analysis assumed a perfectly accurate forecast in either January or April. However, any forecast greater than or equal to Q_3 would have obtained the same response as a perfectly accurate forecast. Thus, at least in some instances, there may be substantial payoff to making inaccurate information available at an earlier date rather than waiting to release accurate information at a later date. There would appear to be, in many situations, a trade-off between accuracy and timeliness. However, it is not at all clear what would be the shape of an iso-value line drawn between level of accuracy and timeliness of the report. The shape is likely to vary from one report situation to the next.

Unfortunately, there is a measurement problem that prevents us from empirically estimating the iso-value curve. The measurement of forecast errors is impossible in cases where the production adjustment model is applicable. Prior production plans are not observable (even *ex post*). In the above example, the true forecast error is zero (i.e., the forecast correctly identified Q_0 as the level of planned production). However, the observed forecast error is $Q_0 - Q_1$ or $Q_0 - Q_2$, depending on when the forecast is released. However, if the forecast had been Q_1 in January or Q_2 in April, the observed forecast error would be zero even though an incorrect estimate of Q_0 had been made. There appears to be no definite relationship between actual and observed forecast errors. Thus, there appears to be no way of determining the level of accuracy for the type of reports depicted in the inventory adjustment model.

Work to date has been with either an inventory adjustment model where producers can-

not adjust output in response to the U.S. Department of Agriculture report or a production adjustment model where no inventories are being held. However, there are numerous situations where a combination of these models will be required for meaningful analysis. The development of more appropriate models is an area of research that needs more attention.

Conclusions

This paper has attempted to identify some of the questions that need to be answered about the value of information. The nature of these questions indicates that there are four types of activities that are needed if we are to make improvements in our agricultural data system.

The first activity is further development of the theoretical and methodological framework for measuring the value of information. Our theories and knowledge about the information requirements of economic activity conducted in a dynamic and less-than-perfect information environment are inadequate to answer some of the questions being raised about our information systems. The second area is expanded collaboration between researchers and managers of public information systems in order to determine what type of information about the value of information is needed for effective management of these systems. Third, program evaluation efforts should provide useful information about ways to improve the operational efficiency of the information systems. The fourth area is impact analysis and extension programs to enhance the general public's understanding about the nature of the benefits generated by these systems.

The focus of this discussion has been on questions related to determining the economic value of public information systems. Developing such measures is a formidable task, and it would be easy to conclude (somewhat prematurely) that dependable, quantitative estimates are not likely to be developed. However, even if this is our final conclusion, the information to be gained by pushing back the frontier in this area is required for answering many of the questions raised above. We will need to understand why such measures cannot be developed. We also will need to identify what other types of information are required to design and manage effectively information systems. Research related to expanding our understanding of the role and value of information in economic activity should be of high priority to economists.

Farm Sector Data: Presentation and Improvement

Kenneth J. Nicol

Economic data for the farm sector are developed by the U.S. Department of Agriculture's (USDA) Economics and Statistics Service (ESS). The economics unit is responsible for outlining the data needs. It works with the statistics unit to collect basic data not available in conjunction with other data projects or from other government agencies. Presently, the economic well-being data are collected and published by the Economic Indicators and Statistics Branch of ESS. These data include the balance sheet, farm income, agricultural productivity, and cost of production series.

Balance sheet data have been developed since 1945 and the farm income estimates from 1914. Both series (and other data as well) were developed to reflect the aggregate sector status for a period in history when many farms were structurally uniform. Changes in the agricultural production sector's structure have made these aggregate estimates less useful as indicators of the economic well-being of the sector. Disaggregations of the sector's aggregate economic data were made reflecting the size distribution based on farm gross sales and geographically based on state location of the farm.

These disaggregations reflect some aspects of these sectors' economic conditions, but other aspects that can substantially influence the true status of the subsector being evaluated, are not reflected. Cyclical patterns in product prices affect farms selling or buying the product but have less effect on farms producing substitutes or not involved in the product's market differences.

During the past ten years, concern about the validity of the data being reported arose and reviews have suggested many changes in the present economic data systems. These reviews and discussions with government staff members and members of the academic community have formed the basis for a set of economic accounts which can overcome many of the shortcomings of the present system (Nicol 1980b). Concurrently, a project to review the data available to modify these accounts has been implemented and a two-phased product produced. Initially, the account formats are being implemented to the extent possible with available data. The second phase was to identify the data needed to implement fully the accounts (Nicol 1980a).

This paper presents a review of the economic data projects and their recommendations. The first item covered is a clarification of the definition of the sector. This is followed by a description of the set of accounts and a discussion of the data needed to implement fully these accounts.

Definition of The Farm Sector

The agricultural production sector for this analysis is defined as the population of all farms meeting the USDA's farm definition. A farm is any establishment producing, or having the potential to produce, a minimum of $1,000 of agricultural products. The activity of the farm to be measured is the total economic activity of the establishment. Activity associated with the movement of a product from site of production for the purpose of transfer of ownership or for movement through a marketing channel or processing facility constitutes movement from the production sector. This distinction is made to separate the component parts of integrated enterprises while allowing the production sector to move commodities to off-farm storage with the intent of influencing market timing. Movement of the product into storage or transport with the intent of altering the locational or physical attributes of the product is associated with the marketing or processing sectors.

Where possible, the production process is being reported separately from the activity of

Kenneth J. Nicol is a consultant-agricultural economist, National Economics Division, Economics and Statistics Service, U.S. Department of Agriculture, Washington, D.C.

the household or farm family controlling the establishment. This eliminates the need to measure other activities of the household and report them as part of the farm's activities.

Identification of the Economic Data

The economic data needed to measure the income and assets of the production sector have been organized into a set of four accounts. These accounts are an asset account (detailing asset type and financing), an asset flow account (reflecting asset purchases and uses), a production or income account (in a value-added format), and a cash transaction account (representing the flow of funds in the sector).

These accounts have been defined so that disaggregations of the aggregate sector can be made using the same account formats. Emphasis for the disaggregations are being put on size using value-of-sales class, geographic location based on states, and product specialization based on the Standard Industrial Classification breakout for the agricultural sector.

These account formats also can be used as a basis for reporting the activity of the farm's controlling institution. These institutions can be defined on legal identity (corporation, partnership, sole proprietor, or other) or on functional purpose (family farms, corporations, or other). Other disaggregates based on the characteristics of the controlling institution also can be made when the required information is available. Examples include operator equal opportunity characteristics, degree of reliance on farming, or tenure.

The Asset Account

The asset account (table 1) brings together the data associated with the farm establishment physical and financial assets, and loan and equity liabilities. The data in the asset account cover only the assets used in the production process (which are owned by the farm business). Assets used by the household for personal living are not included. Assets owned by the service sector and rented, leased, or hired by the farm establishment are not included because they receive a return generated by the income flow of the agricultural production service sector.

The Asset Flow Account

Changes in the asset value in the farm sector result from the interaction of two specific components—prices and quantities. The emphasis of the data in the account concentrates on the physical assets of the sector (table 2). Changes in financial assets are incorporated into the cash transaction account. Asset formation is the sum of fixed-asset formation and inventory adjustments. Asset utilization (disappearance) involves depreciation, accidental damage, sales, and net capital growth.

Table 1. An Asset Account for the Farm Sector

Assets	Liabilities
I. Physical assets	I. Loans
A. Capital	A. Loans for capital purchase
1. Land	1. Real estate
2. Buildings	2. Machinery
3. Machinery	3. Livestock
4. Livestock	B. Loans for operating expenses
B. Inventories	C. Government loans
1. Inputs	1. Commodity programs
2. Work in process	2. Disaster loans
3. Finished goods	3. Other (conservation, pollution)
4. Crop held as CCC loan security	II. Accounts payable
II. Financial Assets	III. Equity
A. Currency	A. Corporate
B. Demand deposits	B. Book value
C. Savings	C. Retained earnings
D. Investment in cooperatives	D. Proprietor's equity
III. Accounts receivable	IV. Total liabilities
IV. Total assets	

The Production Transaction (or Income) Account

This account provides data on the value of products produced and the allocation of the value to inputs and resources. The account reports income in a format that is generally compatible with the national income and product accounts of the U.S. Department of Commerce (table 3). The major function of this account is to measure the output and input of the sector on a value-added basis rather than on a sales and purchase basis. As part of this value-added emphasis, the reporting of CCC loans is being changed. Commodities placed as security for CCC loans previously have been considered as sold. In the new system the commodity is reported as an income source when it enters inventory or is sold. The subsequent transaction with the CCC is a loan secured by the commodity and enters the sector's cash flow account and has no immediate effect on income. It subsequently may affect income as the farmer pays storage and interest or forfeits the loan to the CCC at a loan rate above the present inventory value of the commodity. The activity of the loan received is accounted for in the sector's cash transactions.

The Cash Transaction Account

Not all income, as reported in the production account, is realized as cash available for payment of farm obligations. The cash transactions account (table 4) reports data which illustrate various levels of cash inflow and disbursement. The cash flows of the agricultural production establishment and the operator household are closely related, especially for sole proprietor establishments.

This account reports data which measure the cash components of the production account and supplements these sources and flows with loan activity information. These data will illustrate the impacts of net changes in inventory and CCC loan activity on the operator's available cash levels. For the disaggregated sector report, the data illustrate the impacts of outlays for capital, including land, and how the fixed-payment commitments of some of the subsectors vary in importance and affect the establishment cash available in response to relative price shifts.

Measurement of Operator Well-Being

Measuring the well-being of the farm operator is a necessary component to reflect adequately

Table 2. An Asset Flow Account for the Farm Sector

Formation	Disappearance
I. Fixed-asset formation	I. Capital consumption
A. Own account formation	A. Depreciation
1. Replacement livestock	1. Buildings
2. Construction of buildings	2. Machinery
3. Land improvements	3. Livestock
B. Purchases	B. Accidental damage
1. Land	1. Buildings
2. Buildings	2. Machinery
3. Machinery	3. Livestock
4. Replacement livestock	II. Sales of capital items
C. Valuation adjustment	A. Within the sector
1. Land and buildings	1. Land and buildings
2. Machinery	2. Machinery
3. Livestock	3. Livestock
II. Changes in inventories	B. To other sectors
A. Net value of quantity change	1. Domestic
1. Inputs	2. Foreign
2. Work in process	III. Net capital growth
3. Finished goods	IV. Gross capital disappearance
B. Net value of price change	
1. Inputs	
2. Work in process	
3. Finished goods	
III. Gross capital formation	

Table 3. A Production Transaction Account for Agriculture

Allocations	Sources
I. Intermediate products[a]	I. Sales
A. Purchases of farm products	A. Agricultural products
1. Feed	B. Other products
2. Livestock	II. Other incomes
3. Seed	A. Government payments
B. Purchases from other sectors	1. Program payments
II. Gross value added[b]	2. CCC loans guarantee payments
A. Capital consumption	B. Other
B. Business taxes	1. Insurance
C. Net income at factor costs	2. Interest and dividends
1. Labor compensation	3. Rents
a. Hired laborers	III. Own-account uses
b. Operator and family labor	A. Final demand
2. Return to land and buildings	1. Operator family
a. Rent to landlords	2. Employee perquisites
i. Nonoperator landlords	B. Fixed-capital formation
ii. Operator landlords	1. Breeding livestock
b. Return to operator assets	2. Own-account construction (buildings, land improvement, orchards)
i. Real estate interest	C. Change in inventories
ii. Corporate asset return	1. Inputs
iii. Operator return	2. Crops
3. Capital return	3. Nonbreeding livestock
a. Non-real estate interest	IV. Total Sources
b. Return on operator capital	
c. Corporate capital return	
4. Management return	
a. Hired	
b. Operator	
5. Entrepreneurial return	
III. Total allocations	

[a] Includes inputs for production of ancillary and secondary products.
[b] For compatibility with National Income Accounts, rent paid must be included as an intermediate product purchase from the real estate sector.

Table 4. A Cash Transaction Account for the Farm Sector

Cash Sources	Cash Uses
I. Cash sales	I. Production expenses
A. Agricultural products	A. Intermediate products
1. Crops	1. In sector
2. Livestock	2. Intersector
B. Ancillary products	B. Resource payments
1. Custom work or machinery rent	1. Cash wages and salaries
2. Recreation	2. Cash rents
3. Rents	3. Interest payments
4. Interest and dividends	II. Capital goods purchases
C. Sale of capital items	A. Land and buildings
II. Government payments	B. Machinery
A. Program	C. Livestock breeding animals
B. Other	D. Land improvements
III. CCC loans initiated	III. CCC loan payments
IV. Other loans initiated	IV. Other loan payments
A. Real estate	A. Real estate
B. Non-real estate	B. Non-real estate
V. Financial asset changes	V. Net investments
A. Changes in the sector	VI. Assets of operators existing the sector
B. New assets entering the sector	VII. Total cash uses
VI. Total cash sources	

the status of the farm sector. Many operators supplement their income and cash flow of the establishment by off-farm incomes. The farm operator income account (table 5) presents data to evaluate the farm and off-farm sources of incomes for the operator. Other institutional forms also can be the basis for this type of account. Included may be operators by legal form (corporation, sole proprietors, partnership, and other), operator by reliance on agriculture for income, or other socially and politically relevant category.

Data Needs to Fully Implement the Accounts

Data needed to modify the existing income and balance sheet programs to allow for a more complete report as outlined in these accounts include both sector level and data series issues. The data series issues relate to the definition and reliability of specific data elements. Many of the reported series are estimated from secondary data sources or from arithmetic operations with a set of these data sources. The concerns that arise as a result of this method include complete compatibility of each series, ability to keep the series current, and the possibility of loss of continuity as the data collector's priorities change.

The major emphasis in the rest of this paper will be on the sector level data needs. These needs are by implication relevant to the individual data series. Specifically, the issues include establishment definition, inventory accounting, operator interaction, and subsector disaggregations.

Establishment Definition

The definition of which establishments are included in the sector defines the population of farms for the agricultural sector. The official definition of a farm includes all establishments that produce, or have the capability to produce, $1,000 of agricultural products. This varies from the Department of Commerce National Income and Product Accounts establishment, where the classifications are based on the SIC commodity or commodity group that accounts for at least 50% of the establishment's sales.

At present, much of the economic data for the farm sector are collected at the market channel level and the flow of goods is not identified directly with the establishment marketing or purchasing the commodity.

Inventory Accounting

These data concern three components of the inventory reported on the farms. First is the interaction of the goods held for input or marketing and the goods held as production assets. The second component of inventory is the reporting of commodities held as CCC loan security and is being modified. The third is the identification and measurement of input inventories.

The present accounts report land, buildings, and machinery in capital assets with breeding

Table 5. Farm Operator Income Account

Allocations	Sources
I. Expenses of operators	I. Farm income
A. Dwelling expenses	A. Labor
B. Business associated	B. Return on land
II. Net family income	1. Production return
A. Tax and nontax payments	2. Capital gain on land and buildings
B. Social security payments	C. Capital return
C. Net disposable income	1. Return to working capital
III. Total operator allocations	2. Value change of machinery inventory
	D. Management
	E. Entrepreneurial return
	II. Imputed rental value of dwelling
	III. Nonfarm income
	A. Wages and salaries
	B. Business incomes
	C. Interest, dividends, and rents
	D. Transfer payments
	IV. Total operator income

herds included in livestock inventory. The livestock inventory is to be separated into capital livestock, animals, or birds held for the product they produce, not primarily for sale. The other animals in inventory will be those held for sale, such as broilers, feeders, and animals on feed.

Now the inventory levels for both the capital and production livestock can be identified and values determined. The major data concern is the identification of the flows of livestock. Measuring marketings at the market channel level makes identification of the prior or proposed use of the animal difficult to identify. Is the animal being sold out of a breeding herd as a cull or as a capital item from the production inventory? Young animals will remain in inventory until introduced into the breeding or milking herds. Thus, heifers sold may be for feeders, calf slaughter, or eventual entry into a herd.

The impact of the change in CCC loans, shifting from an assumed sale to a loan with commodities for collateral, requires more data than the previous net change in value of loans outstanding. The quantities of the commodities under loans must be identified as well as the market value of the commodity and its loan rate.

The measurement of input inventories has not been a part of the sector's data reports in the past. The increased use of current cash to purchase next year's inputs before the end of the calendar year potentially can have impact on fertilizer, seed, or fuel purchases. Under the present basis for calculating these items, little fluctuation may occur as their use is based on need rather than marketings. However, as more establishment data become available, especially from surveys like the Farm Production Expenditure Survey (FPES), the potential for error is greater. If the input is considered an expense before the product is marketed or included as inventory, a larger expense is measured with no receipt to offset this outlay.

Operator Interaction

In the discussion on the operator account, reference was made to the need for data which allow for separation of the production establishment and its controlling institutions. Most reference is made to the operator with connotations of the sole proprietor or family farm. Corporation, partnership, or other legal entities also can act as operator institutions. Policy consideration may suggest the separation of the family-held corporation from the multishareholder corporation. Data are needed that separate the assets between those used for production and those used for operator-household living. This would mean separating operator dwellings, household furnishings, and household financial assets from the assets presently identified in the ESS Balance Sheet Project. Separating off-farm income and other income flow associated with the household from the present receipts also is needed. This transfers the imputed rental value of the dwelling to the operator account from the farm income statement. As the needed data are collected, a more accurate representation of the sector production activity and its relationship to the assets will be available.

The household disaggregation can be separate or it can be added directly to the disaggregation of the establishment accounts. The second form of disaggregation needed emphasizes the establishment and is based on its characteristics.

Subsector Disaggregation

Present disaggregations include states and value-of-sales class based on gross sales. Cyclical patterns in relative prices encourage the development of more disaggregation, especially those based on farm type. The state and farm size disaggregations are based on census benchmarks as are the value-of-sales class distribution procedures. The geographic distribution based on states also is developed from the total and disaggregated.

The cyclical patterns in prices causes the duration and magnitude of sales to vary. In order to evaluate the well-being of the various farm establishments, both the relative and absolute effect on various subgroups are needed. The procedure being implemented will base a farm-type disaggregation on the SIC agricultural establishment categories. At this time only the disaggregation of establishments by type, value-of-sales class, and state will be implemented.

Data Collection

The major data issues to be discussed concern the concepts outlined above. Data for each series must be evaluated for accuracy and

compatibility with the other series. Data for the major structural changes are being developed by modifications to existing data sources or by developing new data collection projects. Some of the major effects are discussed by principal area of concern.

Establishment Definition

Little new data are needed except where surveys reflect the entire population of farms on the old USDA farm definition. In many instances, the series used have been modified to the $1,000 criteria.

Inventory Accounting

Most of the flow data for the inventory accounting needs cannot be developed from presently available sources. While the actual levels can be determined, flow data are needed on sales and purchase of various types of livestock by source or use. Modifications have been introduced to the annual FPES of ESS. As planned, these data will adequately reflect the flow on the purchases side. No data are available for the sales of commodities from capital stock. This shortage may be overcome if the Economic Industries Survey (EIS) is implemented next year, as proposed. This survey, in conjunction with the present asset data and the FPES as modified, should facilitate the inventory calculations.

A second data need is the CCC loan activity on a gross basis for calculation of the loan and cash flows. A program has been initiated with the ASCS Kansas City office to receive the necessary data. Emphasis is on the level of loan activity and its impact on flow funds.

Operator Interaction

This section, which would break out the activity of the operator institution from the farm production establishment, has the greatest data shortcoming. Much of the problem is associated with the lack of data other than the Census of Agriculture. This is only available on a five-year schedule and leaves much to be desired in terms of reference and reliability.

Subsection Disaggregations

The major data issue is the availability of classifiers on the survey which collects the data. Type classifiers already have been added to the FPES and are being included in the new EIS. A tentative procedure would be to develop scalers which would distribute the aggregate series.

Data Compatibility

With most every data series originating from different primary data sources, some consideration has to be given to compatibility of the series. Different collection procedures, sampling rates, and processing can affect the accuracy of the calculated series.

A proposal which may solve this compatibility issue would be to modify completely the use and function of the census. The present census could be used primarily to identify the establishment population, stratify it, and develop sampling weights for a series of census follow-on surveys. These follow-on surveys would collect the necessary data and be conducted each year based on a census sample. The annual follow-on surveys could keep track of each establishment and follow it through transfers to maintain its sample.

A program like this would allow for elimination of some surveys presently conducted and, most important, keep all series based on common sampling procedures and population definitions.

Summary

The data for evaluating the economic status of the farm sector have not historically been modified to reflect changes in structure and emphasis of the sector. The project undertaken in ESS has attempted to identify the issues, develop a framework, and implement the system including the collection of new data necessary to quantify the system. At present, the program is in the implementation stage, with the 1979 economic data being presented in the new framework where data permit. Also, new surveys, changes in existing surveys, and discussions with the Bureau of the Census on its role have been initiated to help overcome the existing data needs.

Changing Rural Development Data Needs: Discussion

Peter M. Emerson

In their paper on the changing nature of data needed to understand the economic and social affairs of rural people, Bonnen and Nelson have confronted an important challenge. The strengths of the paper originate from the authors' insistence that a successful data base—including the definition of concepts, inquiry, measurement, and tabulation—can be derived only from a sound theoretical understanding of the relevant information system, and from their explicit recognition that social science data tend to become obsolete as a result of changes in technology and institutions and as a consequence of the "learning" (or adaptive) aspects of the information system itself. Others before them have emphasized that an analytical hypothesis and the data for its empirical test must have the same definitional base (Morgenstern, p. 62–64). However, this still needs emphasizing to some economists and sociologists, who too often show relatively little interest in survey design and data collection, preferring, it seems, to devote their time to the sophisticated manipulation and analysis of inappropriate data.

The authors argue rather convincingly that the deficiencies of existing rural data are due not to a lack of knowledge about data gathering, or a shortage of funds, but to a lack of "an intellectually coherent, widely accepted normative vision of the future of rural society." This, they contend, is caused by our inability to resolve the social value conflicts inherent in rural development and by the very rapid, technologically induced, changes that are taking place in rural society. To help solve this problem, they offer a unique explanation of the evolution of rural development policy as an attempt to remedy imbalances among major social values, together with a more traditional discussion of new technologies and changes in social institutions that have created an urbanized rural society.

Peter M. Emerson is a principal analyst, Congressional Budget Office, Washington, D.C.

The paper provides an interesting conceptual overview of an ideal rural information system. Yet, after discussing the increasing heterogeneity of rural society and the lack of agreement on development objectives, Bonnen and Nelson provide no specific suggestions to assist us in the difficult task of achieving a consensus on rural data needs. Thus, they do not move us much closer to understanding the specific dimensions of a practical rural data base.

I think this shortcoming is related to two major weaknesses of the paper. First, the authors do not discuss the kinds of key decisions in which information derived from improved rural data would find a use. At first glance, it seems likely that information requirements vary greatly among potential users. Small town mayors, regional planners, federal program administrators, policy officials, and researchers are all interested in rural development data. But Bonnen and Nelson do not say whether there are any common threads linking their data needs together.

Without a better understanding of key decisions, of the probability that certain events will occur once a decision is made, and of the payoffs one can expect, there is no way of being certain that improved or new data actually will influence the rural development process and generate a positive return to society. Early in the paper we are told that the nonfarm rural population can no longer be ignored—that we may have devoted too many resources to collecting data on the commercial farm sector. Yet, it has been estimated that each dollar spent to increase the accuracy of USDA crop production estimates will return at least $100 worth of benefit to society (Hayami and Peterson, p. 128). Can Bonnen and Nelson claim a similar return for additional investment in rural development data? Can anyone demonstrate that a further expenditure of funds on social and demographic statistics, say more comprehensive data on rural housing condi-

tions, would be likely to yield a greater return than a similar expenditure of funds to improve a more widely used data series such as manufacturers' new orders or some other important economic indicator?

A second weakness of the paper is that the authors do not categorize, inventory, and critique existing rural data in a manner that leads to specific suggestions for improvement. These data are collected and reported at substantial cost to private citizens, businessmen, and government agencies, and used to encourage remedial action. A first order of business should be to decide how we can improve the existing rural data series. Do certain kinds of data appear too infrequently? Are they inaccurate? A second order of business should be to determine what data series are incomplete or irrelevant. What new series are needed, and what existing series could be eliminated?

Given the lack of agreement on development objectives, the local nature of many rural problems, and the high cost of data, I certainly agree with the authors' conclusion that our current strategy for improving rural data should be experimental and flexible. Bryant has suggested that "emphasis should be on diverse small experimental and pilot projects which would simultaneously develop theoretical concepts for area and regional planning and analysis, their empirical statistical analogues, and methods of data collection" (p. 417). Under such a decentralized approach, attention should be directed to coordination—at the national level, perhaps—in order to guarantee wide accessibility to data and to exchange information about work in progress. Bonnen and Nelson have pointed out that it is important to adopt procedures that will ensure the technical credibility of data, and to guard against efforts to politicize the activities of problem definition, inquiry, and reporting. Nevertheless, I think these problems will be especially difficult to control under a decentralized approach.

Some Concepts for Measuring the Economic Value of Rural Data: Discussion

Thomas A. Miller

Bullock has provided an excellent overview of the information value question as related to rural data. The audience has been guided to a number of concepts or areas that warrant in-depth study. I feel the following two points deserve special emphasis:

(*a*) The primary reason we are interested in the economic value of rural data is to improve our rural data systems. Improved management of public information systems requires a knowledge of the role and value of the information being produced. The management needs of public information system managers should be the focus of future research on information value. What information about the economic value of rural data is really needed to manage effectively these systems?

(*b*) The theory related to the value of information is abstract and complex. It provides little toward a practical analytical framework for empirical analysis. A specific piece of information may be used by many different decision makers in many different ways—an overwhelmingly complex empirical problem. There is no simple formula to measure its economic value.

Beyond emphasizing these points (and others if space permitted), I have no quarrel with the remainder of the paper. Instead, I would like to consider two additional topics: (*a*) the possible structural impact of information and (*b*) the process of choosing between information systems.

Bullock briefly refers to the distributional and structural impact of information—this area deserves considerably more attention. I suspect that public rural data systems have a substantial and often overlooked impact on the structure of U.S. production agriculture, specifically among farms of different sizes.

Beginning in the eighteenth century, American agricultural policy has been to foster a decentralized, atomistic, competitive agriculture. Early in our country's history, an agriculture characterized by numerous small firms was viewed as a primary means of obtaining a competitive structure in the overall economy. Thus, I believe the USDA rural data system was designed in part to promote a highly competitive, atomistic agricultural sector. Any discussion of the role of rural data, therefore, is incomplete unless it considers the question of how these information systems affect the structure of agriculture.

A look at information economies of size is helpful in answering this question (Wilson). Substantial economies of size exist in information production. The production and acquisition of information involves high fixed costs. Furthermore, information production is a risky enterprise, and information producers face both the possibility of producing useless information, as well as the possibility of producing no information. Because outside insurance generally cannot be purchased to offset this risk, a firm must be large enough to internalize the risk of losses from information production before it can produce information through its own data collection and analysis (Riemenschneider).

This combination of high fixed costs and risk leads to substantial economies of size for information production; and information economies of size contribute to firm economies of size. Only large firms can afford to produce and effectively use information, and this activity increases their efficiency. Small firms are unable to produce information—and in the absence of public information—become inefficient in their decision making and lose their competitiveness. Information economies of size thus tend to encourage the development of large firms (created through both horizontal and vertical integration) and may contribute to industry concentration. Many examples could be given; the multinational grain companies may be an example in agriculture.

Thomas A. Miller is with the National Economics Division; Economics Statistics Service; U.S. Department of Agriculture, stationed at Colorado State University.

But society can offset these information economies of size. Public information systems produce a public good to be freely used by all. The advantage of large firms in information production is offset, and small firms become as efficient in the access to information as large firms. If this reasoning is correct, the public information systems of the U.S. Department of Agriculture (USDA) and other agencies producing rural data may currently be one of the major factors slowing the further concentration of agricultural production. If society values a competitive, family-farm type of agriculture, an important value of our public rural data systems may be their contribution to agricultural structure.

Valuing this contribution is difficult. As Bullock points out, "Even if we can establish a cause and effect relationship between the existence of public information systems and industry structure, economic theory provides little operational methodology for estimating the value (or cost) of structural change." So we are left with a challenge. Public information systems may be an important defensive weapon to preserve the family farm. Can the effectiveness of our rural data systems be improved in this regard?

A second topic overlooked by the paper concerns an additional challenge—how decision makers choose between alternative information sources. Bullock notes that the perfect knowledge assumption of perfect competition has led economists to ignore the role of information. My concern is that even when we have considered the role of information, most applied studies have merely assumed decision makers use the existing (or improved or best) information. This practice overlooks the critical real world question: Do (would) decision makers actually use the specific type of information being evaluated or base decisions on some other information?

The Hayami-Peterson work reviewed by Bullock provides a typical example. They assume decison makers base expectations and decisions on one specific forecast, regardless of its accuracy. This assumption guarantees a substantial value to accurate forecasts, if we accept the benefit model. Instead, the assumption should be the focus of empirical research, more than the benefit definitions or quantities involved.

I have designated this process "the information choice model" (Miller, p. 256). Decision makers, farmers, and consumers are often deluged with information and base decisions upon only a fraction of the total amount available. This is certainly true in production agriculture. For any information category, farmers are deluged with information from different sources—USDA, farm magazines, universities, Department of Commerce, *Wall Street Journal*, and industry associations, among others. Decisions likely are made on the basis of some of this information, but never on all of it, and seldom on the "best" information available.

Several factors influence the choice of information to obtain and use in a specific decision-making question: (*a*) the cost and difficulty of obtaining and using each specific piece of information, (*b*) the perceived reliability of the different information sources, (*c*) the economic climate within which the decision maker operates, and (*d*) the nature and importance of the particular decision being made. Each of the multitude of available information sources has a unique acquisition cost as well as a perceived value to the decision. A decision maker chooses the specific pieces of information to use in each decision based on such factors.

Because many public information programs, even rural data systems of USDA, overlap with other private and industry information production systems, the marginal value of a specific piece of (rural) data depends primarily on the extent of its use and then on the private and social value of that use. Assuming the answer to the first question limits the usefulness of answers to the second question. A major part of future research on information value must be to understand how decision makers select information and form expectations based on this information.

Bullock's paper and this discussion outline a formidable challenge. The need, however, is important, and the research warrants increased attention.

Farm Sector Data: Presentation and Improvement: Discussion

Richard D. Rodefeld

While I found considerable merit in many of the proposals advanced here today by Nicol, I also encountered a number of questions or issues that I would like to enumerate briefly for author and audience to consider.

While not questioning the importance of macro and micro data on farm enterprise and operator assets, liabilities, and this change over time, it would be useful to the reader if the author had located the concerns focused upon here within the broader context of farm sector data needs. Other types of economic data and a myriad of noneconomic data may be called for. Also, while enterprises, business owners (or operators), and their families are major components of the farm sector, there are others as well. For instance: the farm population, farm geographic and political areas and communities, and farm work force members who are not farm business owners (i.e., nonoperating farm land and capital owners, hired organizational and operational managers and hired workers). While the need for the types of data Nicol proposes quite likely are obvious to most, a brief review of the reasons for giving high priority to work on these—as opposed to other issues—would be useful.

While Nicol addresses numerous conceptual and measurement issues, others remain. I agree that major changes have occurred in both farm size and specialization—numerous other farm structural changes also have occurred. Examples are the increasing transfer of functions to nonfarm entities, increasing separation of farm business and asset ownership, management, and labor, increasing reliance of smaller operators on nonfarm income, increasing irrigation, changes in input quality, and increasing numbers of farm firms organized as corporations. What is the rationale for identifying increased size and specialization, rather than one or more of these other changes, as the "main changes in structure" that have influenced the effectiveness of present aggregate data? If these other changes have had an impact on this data, then, should they not also be measured more effectively? Also, is there not a need for greater disaggregation of these criteria as well?

It is not yet clear how Nicol has defined the concept of "farm." It can be defined either as a unitary business firm or as an operating unit. These are not the same because firms may have more than one operating unit. There may be growing utility for enumerating and studying both units. While the unit employed has no impact on the national aggregate data reported here, it does have implications for average farm unit characteristics and levels of resource concentration. If the unitary business firm is the proposed unit, then this is at variance with the Census of Agriculture, which enumerates and reports on operating units.

Also, it is not entirely clear how the concept "farm operator" is defined or if it is defined and measured consistently within the farm work force. It may be defined as the "business owner" (i.e., the individual or legal entity that owns) or as the individual(s) or family(ies) in charge of day-to-day operations. Because farm business owners and operational managers are not always the same, it is important to specify which one is the focus and develop rationales, definitions, and procedures to insure unit constancy.

Nicol implicitly recommends that the farm operator i.e., entity in charge, be defined as the farm legal entity, i.e., sole proprietorship, partnership, corporation. It is not clear at the individual level, however, whom he views as the operators of farm partnerships and corporations. In sole proprietorships, it is clearly the solitary individual or family proprietor. Individuals occupying analogous positions in the other two types would be the individual or family partners and shareholders, i.e., the farm business owners. If this is the case, then,

Richard D. Rodefeld is an assistant professor, Department of Agricultural Economics and Rural Sociology, Pennsylvania State University.

to be consistent in the construction of accounts should not the farm-related assets, liabilities, production, and income, of these business owners also be included. As the proposals now stand, there is no logical place either to identify or to report the characteristics of the individuals owning (operating?) partnerships and corporations. If I understand, farm assets owned by a family that rented these to a corporation (in which the family was the sole shareholder) would not appear in the farm asset account. Thus, data reported for proprietorships, partnerships, and corporations will not be comparable.

Another problem here is that the Census of Agriculture defines the "farm operator" as the person in charge of the day-to-day farm activities (i.e., the operational manager). While most are business owners, hired, nonowning managers also are included. There is some evidence of increasing divergence between farm business and asset ownership and management. If so, information reported on farm operator characteristics by the Census of Agriculture and that resulting from Nicol's proposal will decline in comparability with time.

The author suggests at one point that "where possible, the production process is being reported separately from the activity of the household or farm family controlling the establishment." This clarifies data analysis and interpretation and allows for the separate analyses of both entities. Establishment data analysis is complicated by the fact that some establishments have multiple operating units within and across states. These numbers may be increasing. Identifying, collecting, and analyzing the characteristics of "controlling households and families" is problematic since there are farm firms (*a*) where no one nuclear or extended family controls or provides majorities of business and asset ownership and/or managerial decisions, (*b*) which have different business and asset owners, organizational, and operational managers, or (*c*) which are owned (controlled) by other firms (which may or may not be controlled by one household or family).

The analysis of household data (or separation from firm data) could be restricted to those firms owned and controlled by one family. However, this seems inconsistent with Nicol's objective of improving the effectiveness of farm sector data. Some evidence shows increased ownership and control of farm firms by extended families and groups of unrelated individuals.

At one point, Nicol equates family-owned farm businesses with "family farms." While there appears to be a trend toward such a definition in some quarters, it is at considerable variance with most past definitions. While all or most past definitions agree that ownership of the farm business by a farmer is a necessary condition for a "family farm," few or none identify this as a sufficient condition. Other necessary conditions often specified are that the farm business owners also own all, most, or some of the farm land and nonland resources; make all or most of the farms organizational and operational decisions; and, do all or most of the farm's physical labor outside seasonal fluctuations. While high and reasonably constant proportions of all farm businesses continue to be owned by an individual or family—decreasing proportions possess the other traits at high levels.

Briefer comments include the following. First, the treatment and location in the accounts of livestock and crops grown on a custom basis or provided by integrators are unclear. Second, in a recent AAEA-USDA task force report entitled "Measurement of U.S. Agricultural Productivity," numerous conceptual and empirical problems are defined for many of the items included in the accounts presented by Nicol; however, Nicol does not identify or discuss many of them. The AAEA-USDA report may merit some more attention.

Achieving Economic Efficiency and Equity in International Agricultural Trade and Development
(Kenneth Nobe, Colorado State University, Presiding)

The Role of the Multinational Corporation

Ray Goldberg

The purpose of this paper is to evaluate the role of the multinational corporation in achieving economic efficiency and equity in international agricultural trade and development. In evaluating this institution, I prefer broad and rather imprecise definitions: "a cluster of corporations of diverse nationality joined together by ties of common ownership and responsive to a common management strategy" (Vernon, p. 114) or "all enterprises which control assets—factories, mines, sales offices and the like in two or more countries" (United Nations, p. 158). These institutions may be privately, publicly, cooperatively, or governmentally owned and have their principal headquarters in either a developed or a developing country. The strength of each entity depends on its ability to provide market access, raw material procurement, appropriate technology, management, financial packages, risk management, logistics, and coordination to a global food system in an efficient and profitable manner that is responsive to the economic, social, and political priorities of the governments of the nations in which it operates. The strategies of multinational entities are affected more by individual governmental actions than by any other factor.

Governmental Priorities

Each nation is concerned that food, energy, and credit policies fit into its political and social priority system. These priorities include food price stability for consumers and producers; national security and avoidance of too much dependence on outside suppliers; economic stimulation for the general economy and use of underutilized human resources; avoidance of major change in food prices that then become part of a formal cost-of-living increase, which in turn fuels wage and other settlements adding to inflationary pressures; policies that affect the nutrition of a country, such as shipping out needed basic food supplies while importing less essential food items; policies that encourage energy efficient food production, processing, transportation, and distribution; policies that balance human and animal energy with fossil energy, foreign policy issues that give special barter arrangements to political allies, such as the exchange of sugar and oil at nonmarket prices between Cuba and the Soviet Union; balance of payments considerations; ecology requirements; human welfare priorities, given the fact that food for most poor people in every country represents from 30% to 70% of their consumption expenditures; and, finally, the social structure of life—developing insulated policies for domestic commodity prices and protection to maintain small-scale farming agriculture as part of a way of life, and developing methods of reaching the small-scale producer in all countries without penalizing commercial producers who supply two-thirds of the world's food.

Historically, multinational enterprises in the food system sprawl across national boundaries filling a void in the vertical food system from farm supplier to ultimate consumer and carrying on those functions of input technology, farming, grading, assembly, storage, processing, and distribution that either are not performed at all or ineffectively performed by others in the total vertical food system we call "agribusiness" (Goldberg 1968). The fact that these entities have direct ownership of assets

Ray A. Goldberg is Moffett Professor of Agriculture and Business, Harvard Graduate School of Business Administration.

or relations with other entities across national boundaries may seem to be a threat to nations, especially in the sensitive area of agribusiness that encompasses some 60% of the world's population. In the past, some multinational entities were so eager to develop and manage a total vertical commodity system with the help and encouragement of local governments that they soon accounted for enormous percentages of a nation's gross national product (GNP) and exports—and when measured by size alone, were considered to be too powerful when compared to the small national-states in which they operated. Under these conditions, some firms had their assets expropriated, were asked to leave the country, but yet were asked to stay on in advisory capacities and to help manage and develop the potential export sales produced by their previously owned companies.

This paper will not dwell on the past activities of multinational entities but rather will stress the current and future roles multinational firms can play in global agribusiness trade and development.

Theory of Foreign Direct Investment of Multinational Entities

Researchers at Harvard Business School have developed one theory of the growth of foreign investment. Wells notes that "much of the theory of foreign direct investment starts from the assumption that certain firms have some sort of special assets that give them a competitive edge abroad. Various theories take different approaches to determine which firms are likely to have exploitable assets and whether they are likely to exploit those assets abroad through direct investment or by selling them to an enterprise in a foreign country.

"For a decade or so, attention has focused on the nature of the assets that might make a firm competitive abroad. The product life cycle theory proposes one model. According to its premises, firms innovate for their home market, generating skills and knowledge that, in some cases, are then exploitable abroad. Since managers are responsive to their home markets, the nature of a particular firm's advantage is influenced by the characteristics of that firm's national market. Given the nature of the U.S. market, U.S. firms are particularly likely to generate high income and labor-saving products or processes. As incomes and labor costs increase outside the United States, the skills acquired at home by U.S. firms turn into assets that can be exploited elsewhere. The peculiar nature of the U.S. market, as a bellwether of other markets, had led to the particular vitality of U.S.-based multinationals, according to the theory" (Wells 1979, p. 4).

Theory Applied to Multinational Agribusiness Corporations

The agribusiness system has three levels of operation: macroenvironment and public policy; each commodity system in relation to its macroenvironment; and the firm, farmer, or governmental institution as discussed in specific terms of that entity in relation to the commodity system involved.

Agribusiness firms then, both within and between nations, not only have to develop skills and knowledge of the specific operational functions they perform but also have to develop coordinating roles that position them in both their national and international commodity system. They have to adapt their operational and technological skills and their coordinating skills to the level of development that currently exists within and between the nations in which they are involved. Commodity systems do not stop at national borders, and multinational corporations, irrespective of their national origins or their proprietary, cooperative, or governmental ownership, are simply responding to a need to be one type of coordinating link in a global food system. They may have unique corporate strategies for their firms, but these strategies have to be carried out in a manner that is responsive to the goals of the national food systems in which their firms operate. Individual multinational corporations transfer their leadership role on the learning curve of one food system to the system that most closely resembles their home market. In a sophisticated developed market, the infrastructure and the market rules of the game are set forth by strong governments. In an unsophisticated developing market, the multinational firm may have to provide part of the infrastructure and, with the local government's approval, provide a grading and pricing system, as well as the firm's operational and coordinating skills.

As one reviews examples of alternative roles of multinational entities in a global food

system, one must do so against (*a*) a framework of past, current, and future trends; (*b*) a statement of the issues that must be addressed; and (*c*) a recognition that in spite of the consolidation of decision points in most national food systems at every level in the vertical food chain, there is a renewed vigor in the number and strength of multinational entities involved in both the developed and developing country food systems. The magnitude of the internationalization of the world's food system and the strength of the multinational entities is an opportunity to review the kinds of positive and socially useful roles these entities may play. As Galbraith states: "The exercise of power is not a matter of choice but of necessity. It is true of the multinational corporation, and it is wholly and equally true of the large national corporation. . . . Multinational intrusion by the corporations of one country also forces reciprocal actions by those intruded upon. . . . The only reasonable defense of the multinational corporation is now the truth. That it has power must be conceded. The only desirable defense is to hold that such exercise of power is inevitable and, if subject to proper guidance and restraint, socially useful" (pp. 86–88).

The Setting

The internationalization of the world food system became evident in 1972 when the United States sold off its surpluses (now called reserves) and grain prices increased almost 300% with a worldwide production decrease of 3%. Volatile price swings for most commodities have continued and, coupled with volatile exchange and credit rates (Schuh), have had an impact on the kind, number, and structure of the multinational entities in the global food system. The United States and Canada have become the dominant surplus grain-producing area of the world. By the late 1970s the biggest deficit areas were Asia, Africa, and Eastern Europe, and new entrants from Japan and Europe became part of the U.S. grain export market and started to become part of the internal domestic grain system.

The greatest challenge in the world is in the efficient and equitable development of the underdeveloped world food economies. In simplistic terms, the developing countries with 70% of the world's population produce only 40% of the food, have only 30% of the world's income, and only 20% of the purchased agricultural inputs.

Most population growth will take place in developing societies, with three-fourths of the world population being in the present developing sector by 1985. Over half of the population is engaged in the world's food system (agribusiness). In addition, three-fourths of the 145 million farm families in the world are noncommercial (produce primarily for themselves) and have farms whose average size is 5 hectares (11 acres) or less. How to reach these subsistent producers and enable them to become part of a commercial food system is an important factor in our discussion of the role of the multinational firm in international agricultural trade and economic development. Adding to the food pressures of our expanding human population is the fact that, in addition to the 4.8 billion people in the world in 1985, we will also have by that year a livestock and poultry population of approximately 14.9 billion.

World Grain Production and Trade Situation 1980 and Projections

Two-thirds of the world's farmers produce about one-third of the world's grain on their subsistence farms in developing countries. Another third of total grain is produced by developed country exporters (with the United States alone producing 25% of the world's grain production on only 11½% of the acreage devoted to grain production). About one-fifth of the world's grain production is produced by developed-country importers, and the remaining 15% of the world grain is produced by the Soviet Union.

The concentration of grain production in selected countries naturally results in a concentration of grain trade. Total world grain exports increased from the 4% and 25 million tons in the late 1930s to 187 million tons in 1979–80, or 15% of grain utilization and about 13% of production. By the year 2000, grain exports will be close to 300 million tons, with the United States supplying almost two-thirds of those exports.

Because North America is the only significant surplus grain-producing area in the world, U.S. export policy is tied up with the development, export, and import policies of every nation. All U.S. agricultural exports, grain and nongrain, are forecasted to be $40

billion and over 160 million metric tons in the late 1979–1980 export year, providing the United States with a positive trade balance of $22.5 billion. At the same time, our imports are estimated to be at an all-time high of $17.5 billion, with the enormous responsibilities of providing market access for both developing and developed countries to the U.S. market. By 1990, of the estimated $100 billion of U.S. agricultural export sales, $50 billion will be to the middle to upper income developing countries. These numbers are most important when one realizes that many of the procurement decisions are being made by governmental entities, that flexible long-term contractual relations will become more important in our future trade policies, and individual multinational firm rules will change.

In the future, our relationships with both the developing world and centrally planned economies could become even more intertwined. As Leontief noted in *The Future in the World Economy*, as incomes and populations rise by the year 2000, world agricultural production should increase by three to four times the 1970s' level and per capita output should double. The average total growth rate for all developing regions was projected to be 5.3% per annum from 1970 to 2000 and 1.6% per annum for the developed world. By the year 2000, it is projected that one out of every four cultivated acres in the United States will be producing food for the developing world. As it is now, one out of every three cultivated acres in the U.S. is currently providing production for exports. Is it any wonder that farm cooperative multinational firms are emerging with such a major market affecting American agriculture? It is estimated that in 2000, one out of every two acres could be providing production for exports, with some of the remaining acreage being devoted to energy farming.

U.S. Response

The U.S. response to the agricultural economic development needs of the developing world historically has been a confused mixture of surplus disposal and aid programs: of unique export and import concessional sales and markets, rapidly expanding export sales and grain-trading quantity agreements in the 1970s, and of financial and technical support directly from the United States or through the World Bank, Overseas Private Investment Company, or through private groups such as the Latin American Agribusiness Development Co. (LAAD) or individual private and/or cooperative firms, and the encouragement of commodity agreements for sugar, wheat, and feed grains.

Impact on Multinational Firm Strategies

With the broad projected changes in world agricultural trade, the dramatic volume and dollar changes that occurred in the early 1970s, and product life cycle theory of foreign direct investment, what roles can we expect multinational corporations to play?

The Grain Traders

Multinational grain trading has its sourcing focus in North America. As American surpluses dwindled in the early 1970s, a buyer's market became a seller's market. This new market brought new entrants into the export market and brought the potential of increased profit for some exporters. New firms, such as Cook, became market share leaders in 1976, only to misjudge commodity export markets and end up selling out. Cook saw its profits deteriorate from $22 million in 1975–1976 to a loss of close to $81 million in 1977, with a subsequent sale of its grain and processing operations to Mitsui and Marubeni, Japanese multinationals, and to Gold Kist, an American farm cooperative. These sales were representative of new entrants into the grain-exporting business from the grain deficit areas of Southeast Asia and Europe.

Zen-Noh. One example is that of the Zen-Noh Company.[1] This Japanese Cooperative[2] represents in one commodity or another the five million farmers of Japan. Its selling and procurement functions amount to over $25 billion a year.

One long-term objective is to develop an international Agribusiness Cooperative Center for the mutual benefit of all farmers. More specifically, it has trading and development relations with cooperatives in developing and developed countries all over the world. Recently (fall of 1979) its decision to build a

[1] Many of the examples in the following sections are from Goldberg et al.

[2] Throughout this paper, farm cooperatives describes those created and managed by farmers, rather than "farm cooperatives" created by governments and managed as semipolitical institutions.

terminal grain elevator in the United States had added to its relationship with the U.S. farm economy.

Alfred C. Toepfer International. Intrade, a joint American-European Cooperative,[3] has entered into an agreement with Toepfer, a German holding company, to create a new agricultural commodity-trading company named Alfred C. Toepfer International. Although farmer cooperatives handled 40% of the U.S. grain domestically, they currently handle only 10% of all grain exports. Intrade hopes to get farmer cooperatives more directly involved in the export market, to pass trading profits back to their farmer members, to improve their competitive position, and to promote integration and development with farm cooperatives in both developing and developed countries. (20% of the world's population belongs to one or more cooperatives, which are becoming a major international force, see Craig.) Nevertheless, the cooperative-based Intrade will trade with all types of entities as well as cooperatives and source supplies from the least-cost nation, thus improving the efficiency of the system and providing direct competition with proprietary multinational corporations. Like Zen-Noh, they will also engage in improving and helping the infrastructure and operations of developing country trading partners, be they sellers or buyers.

Japanese Trading Firms. The Japanese multinational proprietary corporations play a significant role in the Japanese mixed feed industry and work closely with the Japanese government. One creative activity of Japanese multinational firms is the development of both an external and internal market system, through a Japanese-Thailand Corn Agreement existing since 1961, which provides a mutuality of interest for both the Thai corn system and the Japanese feed industry. The existence of the agreement, and an assured market access for Thailand during a period of global corn surplus, provided a market incentive that led to a more than threefold expansion of Thai corn production during this period (with occasional declines due to unusually adverse weather conditions). Not only was production increased but, because the agreement was tied to the price of the nearest trading month for corn on the Chicago Board of Trade, price discovery in terms of a published and broadcast price was more readily available to producers.

In essence, commodity trading firms do not just buy cheap and sell dear, but rather recognize that they are an integral part of the food policies of the countries in which they operate and help, in cooperation with the government, to improve the efficient handling of the commodity through equitable agreements that, in turn, provide a price stimulus for local developing and developed country producers. The firms involved are heterogenous, and thus they can have an on-farm or off-farm orientation, a producing or consuming country orientation or a developed or developing country home of origin. In a sense, the internationalization of the world's food system has created an awareness in all the participants that they can create a multitude of international arrangements to be part of that system. In the early steps of development, with backward and forward coordination taking place, an increase in the number of participants directly active in the global food system provides a broad competitive market. One must be on the alert for the next stage of development, which may lead to new types of consolidation requiring new global, regional, and national market rules and regulations. At the same time, these new entities recognize that it is not enough to be just the most efficient operator, one has to be the most innovative in responding to the equity needs of the exploding developing country markets and involve the small-scale producer in the process.

Foreign Investors from the Third World

One interesting development concerning the current and future role of the multinational firm is the increasing number of such firms with origins in developing countries. Professor Louis T. Wells, Jr., of the Harvard Business School faculty, is a leading authority in this area. Much of the following discussion is based on five of his recent publications. Wells indicates that approximately 1,100 foreign-owned projects in less developed countries have thus far been identified as having parents in other developing countries. These projects represent only a fraction of such investments, since they are generally understated in official

[3] The partners include from America: Gold Kist, Land O'Lakes, Agway, Indiana Farm Bureau, Land Mark and Citrus World. The non-Americans include United Cooperatives of Ontario (UCO), Canada; CEBECO-HANDELSTAAD, Netherlands, Deutsche Raiffeisen-Warenzentrale Gesellenschaft (DRWZ), Germany; Cetreide Import Gesellenschaft (GIE), Germany; and Union Nationale des Cooperatives Agricole De Crex Cereales (UNCAC), France.

documents. As in the case of farmer cooperative multinational activity, their growth rate is much faster than that of their competitors who happen to be proprietary corporations.

These developing country multinational firms seem to be uniquely well-positioned to have an advantage in the following areas: (*a*) the creation of small-scale technology as a by-product of Western technology adapted to developing country conditions and to the need to use more labor-intensive technology; (*b*) the ability to create flexible processing operations that can produce multiproducts and multimodels for the internal small-scale markets of most developing countries; (*c*) the ability to modify operations to use local raw materials of less sophisticated quality to avoid external sourcing problems; (*d*) the ability to move from one developing country to another to avoid quotas on exports, e.g., quota hopping; (*e*) the ability to seek out countries that provide access to restricted markets, e.g., investments in Mauritius to gain access to the EEC; (*f*) the ability to develop (as do their advanced country competitors) vertical integration arrangements when long-term contracts break down because of unusually volatile markets; and (*g*) the ability to integrate forward into developed country markets by acquiring not only the value added and market distribution network but also branded franchises, such as the Brazilian Cooperative purchase of Hills Bros. Coffee in the United States.

Wells also points out that in spite of some well-publicized foreign projects undertaken by state-owned firms from the developing countries, a vast majority of the investments emanate from privately owned companies. In fact, as a matter of public policy, farmer cooperatives have been encouraged by national governments to play a more active role in the global food system so that producers may have a more important part in these systems. It would seem that public policy also will encourage developing country multinational firms to expand because of their special awareness of the problems of scale and of underutilization of labor as well as their contributions to an even more competitive global food environment.

Multinationals and Government Joint-Venture Changemakers

Just as there are leading changemakers at the indigenous and producer level, so there are unique multinational changemakers who are providing a much needed leadership in developing-country food systems. Two such changemakers are Tate & Lyle and Booker McConnell, Ltd. Tate & Lyle represents the evolution of a sugar firm that has moved from reacting to local governmental programs to actively trying to anticipate changes and provide collaborative leadership to the local private and public decisionmakers in the food system. Its goal has been to create national companies run by local nationals but with strong bonds to the Tate & Lyle group.

One of the best examples of a similar agribusiness approach is Booker Agriculture International Ltd. and its Mumias sugar scheme in Kenya. Even the severest critics of agribusiness applaud Booker's approach in the Mumias project and consider it one of the most important ways multinational corporations in agribusiness can make contributions to developing food economies. As Susan George states in her book, *How the Other Half Dies*, "In another sense, the success of Mumias is a further argument that multinational agribusiness must be controlled, for when it is, it has a definite contribution to make. . . . it appears to be an excellent specimen of the contributions business *could* make to development if *social goals*, not merely profitability, were present in the project from the drawing board to the actual operation" (pp. 182–5).

Such is the case of Mumias, which originated with the Kenyan Government requesting help and input from Booker on the project. Booker carried out a pilot project and, with the government, outlined a program to create a whole sugar system involving over 16,000 small-scale producers and 2,500 other employees, on a managing agency basis that compensates the company for productivity and efficiency.

Multinationals Improving the Infrastructure

Just as C. Itoh acted as a catalyst in the development of the Thailand corn economy through the Japanese-Thai Corn Agreement, other multinational firms have improved the food systems of their host countries through their operations in various foreign environments. One example is the case of Rafhan Maize, a CPC International joint venture in Pakistan. This company was formed to help in the expansion of a local corn-processing industry. In order to expand the industry, Rafhan Maize at

the government's request helped to provide an extension service to the local corn producers. They improved the corn technology of many farmers by providing a local market, guaranteeing a minimum price for corn (even before it was planted), and provided credit, seed, fertilizer, and storage. In many cases, the new varieties of corn provided two crops where only one has been grown previously. Rafhan also provided a grading system where none existed before. The processing industry provided local oil and starch products, which had been imported previously.

Private Development Groups—Latin American Agribusiness Development Corporation

LAAD is a profit-oriented private investment and development company. Incorporated in Panama in early 1970, the corporation develops and finances modest-sized private ventures in the fields of agriculture, animal husbandry, forestry, and financial services in Central and South America and the Caribbean. It helps develop local entrepreneurs to improve local food systems.

New Arrangements

Agribusiness multinational corporations bring not only their unique production, procurement, processing, marketing, financial, and managerial skills to other nations, but they have been able to transfer the coordinating skills and arrangements from one environment and adapt them to another. One example is the Foods Division of The Coca Cola Company, which developed a unique arrangement with a Florida cooperative (Florida Orange Marketeers) so that the cooperative supplied the oranges, the Minute Maid Company of the Foods Division and the cooperative shared profits based on processing and marketing, and the ultimate distribution, advertising, and promotion was left to the corporation. In Brazil, the Foods Division of The Coca Cola Company has a similar arrangement with local orange growers who operate the raw material procurement operation; the growers and the company jointly share in the packaging operations and the marketing is the function of the multinational corporation.

New Entrants

Because of the worldwide energy crisis and its impact on trade gaps, a new player will probably become more important in global agribusiness: the multinational oil company. In view of their financial surpluses, the oil companies have to consider what investments in addition to reinvesting in fossil energy might be appropriate for their firms. Given that they now see the potential of ethanol and biomass energy, as well as the fact that they handle commodities, have a logistic system, and work with both developed and developing countries, it would be logical to assume that they would be prepared to invest in global agribusiness.

Financial Implications

Finally there are major financial problems that require multinational corporate aid in the development of new financial instruments that are more flexible in their payout to reflect the continuing volatility of the global commodity-oriented food system. According to the World Bank, the 1980 total disbursement of capital is estimated to be \$70 billion, 1985 estimate \$122 billion, and 1990, \$184 billion. Private loans would represent about 40% of this flow. Compared to such inflows is a trade gap of the non-oil developing countries projected to be \$120 billion in 1990. Based on Mutsaers' estimate, if basic economic growth rates are to be realized, repayment of principal and interest payments by the developing countries would need to rise during the 1980s about five times and would bring the total deficit to be financed by 1990 to \$470 billion, of which medium- and long-term loans would need to provide \$320 billion (p. 1).

Conclusion

The global food system is in ferment. A heterogenous group of multinational entities are being created to respond to the market access, raw material procurement, appropriate technology, managerial, financial, logistical, risk management, and coordination needs of the many nations that make up our global food system. These entities recognize that they must perform their functions in ways that are responsive to an equitable pricing system for producers and consumers, that are performed in a manner that helps the subsistent producer and low income consumer become part of a commercial food system. So far, private and cooperative multinational firms have been most creative in structuring such entities. The traditional ownership patterns of control-

ling assets is changing to a management of complex relationships without automatic ownership of assets. The development of managers with a breadth of vision to perform their functions in a practical manner but with a responsiveness to the economic, political, and social priorities of the nations in which they operate is a primary responsibility of these firms. The role of the multinational corporation is to be but one alternative institution that coordinates a global food system. The fact that farm cooperative multinationals and developing country multinationals are increasing their market shares in the performance of the various functions of a global food system is encouraging evidence that at least for the present there is little to fear of domination by any one type of multinational entity. On the other hand, these entities, irrespective of ownership form and/or origin, are powerful and are also intelligent enough to heed Galbraith's advice that they be socially useful. The specific entities cited in this paper give evidence that there are many examples of the new breed of socially useful, as well as functionally practical, multinational corporations.

The Role of Export Cropping in Less Developed Countries

Jimmye S. Hillman

Discussions about agricultural exports from poor countries (LDCs) often involve two diametrically opposed positions: those that view exports along with agribusiness and associated phenomena as causing most of the problems of poor countries; and those that believe not only in an export orientation for the less developed countries (LDCs), but that agricultural, raw material, and food exports hold a key place in the economic development of many of them. At the outset, I should like to recognize the danger of generalizing because of the diversity of LDCs. Developing countries vary greatly in size, resource endowments, economic and political systems, policies, and economic stability, for example. This means that many of the issues surrounding LDC exports, indeed all LDC trade policies, are empirical questions that require considerable research and frequently involve country-specific answers.

The term "export cropping" appears to be the latest etymological variation of a terminology which has been around quite a long time; viz, "monoculture," "cash cropping," and even that old colonial fallout, "commodity scheme." Export cropping is defined here as the pattern of specialization in production and distribution evolving out of comparative advantage and the capitalistic-oriented, development-trade model.

Is the recent criticism of export cropping just a rallying point for world food and hunger campaigns and the politics of food, and for the developmental processes necessary to obtain food? Or, do the critics of export cropping imply something more fundamental about traditional economic and social organization, human actions, and values? My feeling is that it is the latter. In any event, it appears that the current interest in export cropping has been accentuated by the increasingly intense interest in food and nutrition. Titles such as *Food First, How the Other Half Dies, Feeding the Few, Diet for a Small Planet, Bread for the World,* and *Overcoming World Hunger* have generated a great amount of interest in food and development problems. Much of the literature critical of export cropping is highly rhetorical and is characterized by general solutions and sweeping indictments. In *Food First* (Lappé and Collins), *How the Other Half Dies* and *Feeding the Few* (George), for example, the authors find fault with almost every development organization and imply that the entire social system needs change, particularly in the developed capitalistic countries.

The Presidential Commission on World Hunger pointed out that the major world hunger problem today is not famine or starvation, but the less dramatic one of chronic undernutrition. This view is corroborated by Seckler. Sloganeering and rhetoric about the impact of export-cropping policies should not obscure the need for programs to enhance agricultural production, rural employment, and nutritional improvement in the LDCs. My key point is that export policies must be part of these programs. It will be argued that production and trade policies centered around export-led growth make a positive difference for LDCs, because growth in incomes is the principal means of improvement in rural welfare, and exports provide an important means to generate income. The argument will be somewhat tempered by considerations of self-sufficiency and food security, and a recognition of the importance of trade liberalization by the developed world. Nor are these comments meant to detract from the importance of technological change and increased efficiency in production for the domestic market in the LDCs.

Thanks are due especially to Roger Fox and Eric Monke for their help on basic ideas and construction.

Comparative Advantage

The notion of comparative advantage is the centerpiece of traditional trade theory and the principal rationale advanced by proponents of export cropping. The thrust of the theory is premised on the recognition that nations, or regions, are differentially endowed with resources, including human capital. These differences also extend to asset ownership, taste-endowment and related demand-creating attributes. Production and specialization, including the exploitation of economies of scale, lead to increased levels of world output, and exchange of this increased output represents the gains from trade.

Proponents of export cropping argue that by removal of the restricting assumptions of the traditional two-country, two-commodity model, the dynamic forces of trade promote and facilitate the complex processes of economic development and add important dividends, such as access to world food supplies. They argue further that trade encourages technological innovation and raises worker skills. Increases in the range of goods that can be purchased stimulates new wants and can create new areas of production or higher productivity. Only exports can enable low income nations to pay for those goods and services necessary for development but which they lack the capacity to produce. Finally, exports provide an important source of direct government revenue in many countries, as in Malaysia where, in recent years, 30% federal funding has derived from export taxes. Curtailing exports and trade would mean seriously undermining the fiscal positions of nations which are without alternative sources of taxes. In sum, trade, through the execution of the principle of comparative advantage, brings not only static gains to a country but also acts as a stimulus to growth.

Table 1 presents some data from the Food and Agriculture Organization (FAO) which demonstrate the practical logic of comparative advantage. These figures purport to show that LDCs would experience a foreign exchange loss (and farmers a loss in gross and net revenues) if they switch land out of traditional export crops into domestic production of food crops at present imported. Such figures, though used here to suggest a basis for specialization and trade, can provide only crude generalizations because they assume static technology, do not take into account

Table 1. Foreign Exchange Value of Selected Crops to Developing Countries

	Export Unit Values per Hectare (US$)[a]	
	1963	1975
Coffee	320	769
Cocoa	127	436
Tea	1,001	1,197
Tobacco	719	1,250
Sugar	352	1,462[b]
	Import Unit Values per Hectare (US$)[c]	
Wheat	73	210
Rice	83	283
Barley	48	145
Maize	58	169

differential conditions of soil and climate for alternate crop use, ignore differences in input costs, and assume homogeneity of labor and static employment conditions. Nevertheless, the differences in the above qualifications would have to be very large indeed to overcome the substantial differences in gross revenues evidenced in table 1.

Table 1 also indicates rather substantial increases in the prices of agricultural products, and this trend is confirmed by more aggregate data. Furthermore, during the 1960s and 1970s there appeared to be little, if any, deterioration in the average terms of trade between agricultural and manufactured products. The World Bank price index for manufactured goods imported by LDCs increased by 246% between 1961–78. The FAO price index of LDC agricultural exports increased by 280%, while the price index of food imports increased by 250%. Thus, there appears little basis to suggest that countries have much to gain by diminishing their levels of agricultural exports.

Such figures, even if they provide a broad indication of the imprudence of shifting into food and out of export crops do not necessarily provide a basis for recommending further concentration on export cropping. Such caution has been neatly summarized by Lewis in a brief commentary on the factoral terms of trade as between the tropics and temperate zones (1978, pp. 14–20). He argues that the

tropical countries cannot benefit much from productivity increases in export commodities because of inelastic demand. Instead they must raise tropical productivity in the commodity common to all countries, domestic foodstuffs.

Given the prominence of food crops in the agricultural sector of most LDCs and the limited potential increases for most agricultural exports, the brightest prospects for growth may well lie with domestic food crops. But the key issue for LDCs will involve their ability to develop new varieties and technologies that will increase factor productivity sufficiently to induce comparative advantage and thus make food crop production economically attractive to farmers without major government subsidies. Research and development expenditure in tropical agriculture traditionally has been oriented toward export crops, while many of the prominent food crops—maize, millet, sorghum, cassava (manioc), yams, beans—have received little attention. Even for commodities which have benefited from research investment in recent years, such as rice and wheat, substantial potential remains. The potential for rainfed rice, for example, which comprises over 30% of Asian production, has yet to be intensively researched (Barker and Herdt). In addition to the development of improved varieties, increased productivity in food crops frequently will require new input technologies which make use of simple mechanical inputs to substitute for labor. While the potential for increased productivity may be unknown, it is clear that without major increases in research and development expenditures little improvement can be expected.

Instability of prices and the resultant erratic earnings from export crops present further problems for LDCs. There is substantial truth to the proposition that relatively low, short-run elasticities of supply and demand for the export crops of LDCs result in significant price instability. But government policies in the countries themselves contribute significantly to that instability. Some research on the subject shows, however, that while price instability imposes costs through its effects upon the allocation of resources, it is not obvious that it has been the LDCs that have lost from the income transfers brought about by convulsions such as the upsurge in agricultural prices after mid-1972 (Johnson 1978, p. 198). Other research on uncertainty provides grist for those who are unwilling to follow the pure theory of comparative advantage to its logical conclusion.

Problems in LDCs related to those particular crops whose prices are low and declining in real terms and to slow market growth and declining purchasing power are more intractable than the problem of price instability.

A number of studies using varying methodologies have attempted to analyze comparative advantage empirically. One such study analyzes a small, open economy—Senegal—under the assumption of aversion of economic policy makers to international price risk (Jabara and Thompson). The results show that a country may, indeed, be better off in a more diversified position than by taking the route of traditional comparative advantage. That is, under assumptions which include international price risk, a policy of free, undistorted trade may not be the first best policy for all small countries to follow. The authors of this study admit, however, that such programs should be consistent with a broader concept of comparative advantage which recognizes that risk has a subjective cost.

Another study of Senegal comes to somewhat different conclusions, more explicitly favorable to comparative advantage and export cropping (Pearson, Humphreys, Monke). The analysis shows that domestic production requires an average subsidy of 67% of c.i.f. prices, and that if the government desired protection against fluctuations in c.i.f. prices, a financial buffer fund is clearly more efficient than a domestic production subsidy. Only if rice were unavailable on the world market at any price does the alternative of domestic production, or diversification in food production, appear economically rational. Furthermore, the argument goes, domestic production itself is not free from uncertainty.

Self-Sufficiency in Food?

If comparative advantage is the centrifugal economic force propelling developing countries into the export world, then self-sufficiency in food would appear to be the centripetal political force which is drawing those countries inward for domestic solutions to their development problems. Self-sufficiency in food is viewed by many countries as the only alternative to export cropping and comparative advantage, and they place it at the

heart of their national development and their food and agricultural policies.

Provisional self-sufficiency estimates by FAO (1975) presented in table 2 for 103 countries (only 5% of the world population was not included) show that 3 billion of the world's population of 3.7 billion at that time lived in countries, each of which was at least 95% self-sufficient in kilocalories (O'Hagan). Somewhat unexpectedly, developed countries were less self-sufficient than developing countries, a fact which should not be lost on the export-cropping critics. Admittedly, the statistics presented in table 2 provide only part of the picture.

The current emphasis on self-sufficiency for food in developing countries is reminiscent of the rush toward import substitution of manufactures in the 1950s and 1960s. The most frequently articulated reasons for self-sufficiency involve conservation of scarce foreign exchange, protection of an economy against instability arising from fluctuating import prices, and insulation of a country from presumed political vulnerability associated with dependence on imports. Self-sufficiency, in short, often tempers comparative advantage because governments are responding to uncertainty in food supplies, depleted foreign exchange reserves, and poor income distribution with measures of direct intervention.

The North-South Commission, for example, suggests that in a broad perspective, self-sufficiency in food must be the aim of the world's major regions (North-South Commission, p. 93). This and other works emphasize that the concept of self-sufficiency in food is an optimum development strategy for developing countries (FAO 1975, 1979; O'Hagan).

Demands for self-sufficiency rarely address the appropriate degree of self-sufficiency, nor do they consider the costs involved in attaining self-sufficiency. But these factors are frequently the crux of the matter. Large-scale subsidization of agriculture is an expensive business for a country with 50% or more of its labor force on farms. Also, production costs in farming can rise rapidly when output is stimulated in regions badly suited to such farming. Variability in output can be more severe when self-sufficiency levels are higher than warranted by natural resource endowments. Moreover, imports of production inputs and investment goods for agriculture can put almost as much strain on the payments position as would importing the foodstuff itself. Despite self-sufficiency and export-cropping rhetoric and genuine aspirations, these factors suggest that a continued expansion in the absolute level of food imports by developing countries might be required due to the constraints on domestic budgets (Josling).

In conclusion, whether more or less self-sufficiency is desirable becomes an empirical question for each country, demanding more objective analysis. First of all, the costs of a self-sufficiency policy must be given more emphasis. Achieving improvements in income distribution involves both income sacrifices and transfers from urban consumers through higher food prices—thus, the urban poor suffer. While government policy discriminates against food production in some countries by taxation of inputs and outputs, it is question-

Table 2. National Food Self-Sufficiency, 1970–72

	Food Surplus Countries (Over 105% Self-Sufficient)	Approximately Self-Sufficient Countries (95%–105% Self-Sufficient)	Food Deficit Countries (Under 95% Self-Sufficient)
Developed countries

able whether strong policies of self-sufficiency can be pushed in most countries before effective research and development programs are established for domestic food production and distribution. On the other hand, it must also be noted that current export levels in many developing countries do not reflect free trade, and distorted policies may in some cases overemphasize exports (e.g., by subsidies) or restrain export development (e.g., by export tax schemes).

Export-Led Growth

A policy of export-led growth in developing nations—including agricultural commodities—is closely tied in with global economic trends. Trade in agricultural goods is inevitably linked with trade in nonagricultural goods; thus, the market for agricultural products of developing countries is inextricably linked to the world market for their manufacturing products. World industrial production grew at an average rate of just under 6% and world agricultural output at a rate of just under 5% during the period 1953–73. These were double the rates of the four decades just prior to World War I. World trade, along with agricultural trade, jumped in a similar way. Total exports of the developing countries rose by nearly 7% per year between 1960 and 1973, or faster than the annual growth rate of their gross national product (Lewis 1979). Manufacturing exports from developing countries increased even more rapidly during that period—at more than twice the rate of gross national product (GNP). Thus, export-oriented policies of developing countries, buttressed by high growth rates in the industrial nations and major trade liberalization in those nations prior to 1974, were generally successful.

A variety of studies have demonstrated that growth performance has been more satisfactory under export promotion strategies than under import substitution strategies. Krueger concluded that countries which adopt an export-oriented trade strategy generally have experienced rapid growth of traditional exports, but even more rapid growth of nontraditional exports. The relationship between export performance and growth has been tested by the experience of many countries for (*a*) rates of growth of real GNP and of exports, (*b*) real GNP net of exports and exports, and (*c*) for rates of growth of GNP as a function of rate of capital formation, aid receipts, and export growth. Detailed studies at the national level, both for different time periods in the same country (for example, the Philippines and Turkey) and of countries (for example, on the positive side: Brazil, Colombia, Ivory Coast, Korea, Malaysia and Taiwan; on the negative side: Argentina, Egypt and India) provide further support for the strong link between export performance and growth rates.

Why such a difference in growth performance under export promotion strategies as contrasted to import substitution? Krueger (p. 288–92) and the studies she reviews point out (*a*) that technological-economic factors imply an overwhelming superiority for development through export promotion; (*b*) that differences in growth rates have often resulted, not from the choice of trade strategy as such, but rather from excesses in the ways in which import substitution policies were administered; and (*c*) that policies adopted in pursuit of an export promotion strategy are far closer to an optimum than are those adopted under import substitution.

How to come by increased efficiency and development in a developing country's agriculture is the problem which concerns both export croppers and those interested in food self-sufficiency. Johnson (1980) has given a general policy recipe which stipulates (*a*) adequate incentives for farmers through prices of products and imports that have a reasonable relationship to the real alternative values in the international market; (*b*) the development and availability of useful technology that will make possible higher levels of productivity of agricultural resources, both from land and labor; (*c*) adequate and reliable supplies of modern inputs for farmers; (*d*) access to national and international markets for farmers; (*e*) a significant improvement and expansion of irrigation; and (*f*) economic, political, and social systems which permit the farm population to share in economic growth. The importance of the latter factor, equity, has been emphasized by Schuh, who asserts that farm and rural people in developed countries are poor and inefficient because their governments have seriously underinvested in them, particularly in terms of health and education. Instead, governments have followed inappropriate policies which keep farm prices low by decree and which intervene in product markets to correct problems rooted in factor markets.

Ultimately, food security is one of the real reasons countries turn toward self-sufficiency schemes rather than let comparative advantage and free trade run their course. In Egypt, for example, like many developing countries, the major policy issue is whether to strive for self-sufficiency or rely on international trade for food. Egyptian policy currently favors the latter. A popular definition of food security in Egypt is to strive for a balanced agricultural trade—to have cotton and other agricultural exports pay for the imports of food. (MASI-GROUP).

Hence, a policy of export-led growth, in addition to dealing with problems of increasing productivity, employment, and equity in the agricultural sector, also must deal with the problems of economic uncertainty and the instability in food supplies. The principal controversy surrounding food security relates primarily to man's policy role, not to the limitations of man and nature to produce enough food. Export-cropping critics point to the world's physical resources and man's technical skills and imply that for people to go hungry is not a scourge but a scandal. Man is to blame; the system must be changed. Others, looking at the same situation, say, indeed, man is to blame, but it is man the political manipulator who intervenes in the production and distribution system, and not man the farmer, or scientist, or extension worker, or food distributor. Experience and evidence tend to substantiate the latter view.

In historical perspective, food security has increased because of economic development and the resultant international distribution processes. Various studies have shown that world economic growth and associated technological changes have greatly increased food security over the past century. Dramatic changes in communication and transportation, coupled with enlightened social attitudes toward the alleviation of starvation and hunger, have combined to assure access to food supplies for most communities and regions. An apparent reduction in the variability of world grain production, along with increased per capita incomes for much of the world's population, have combined to give them access to food reserves through trade and have added to world food security.

Trade Liberalization

Before proceeding to specifics about trade liberalization, it is necessary to emphasize that our scenario for export-led growth of LDCs is linked by trade to the speed of growth in the developed countries (DCs). In primary commodities, the relationship has been close for a long time (Lewis 1979, p. 9). The terms of trade also fluctuate with the growth rate of DCs within the limits permitted by the high elasticity of supply of tropical raw materials and by the link between agricultural materials and the price of grains. Since World War II there has emerged a new trade linkage involving exports of manufactures from LDCs to DCs, which depends on the rate of growth in the DCs, not merely because the growth affects consumer demand, but also because it influences the willingness of governments in the industrialized world to allow such imports to enter. Many LDCs have found that the effect of these links is multiplied by the further link between prosperity in their export trades and industrialization for their domestic market. Growth in the industrialized world is, therefore, a necessary condition to induce increased exports from the LDCs, but there must be trade liberalization as well, especially decreased barriers to exports of manufactures from the LDCs to the DCs. Given the demonstrated links between growth and trade, what the LDCs need is (*a*) that the industrialized world should grow as fast as possible, and (*b*) that it lowers its protection against goods from LDCs, especially against processed agricultural products and manufactures.

A large number of products are subject to trade barriers from industrial countries, which result from a desire to protect their own domestic production. Conclusions from a recent study undertaken for FAO (Valdes) are in general accord with several other studies which examine the impact of agricultural protection. That study concludes that a 50% reduction in the protection given to food and processed food and feed commodities in OECD countries would lead to a $3 billion increase in the annual exports of the fifty-seven most populous developing countries. Such an increase would amount to approximately 15% of total exports of the seventy-nine commodities included in the analysis. Furthermore, full trade liberalization in the commodities would about double the gains.

The potential gross benefit to the fifty-seven developing countries from a 50% reduction in protection—expressed in annual flows for the main products concerned—are shown in table 3. Sugar, beef and veal, and wine account for two-thirds of the overall increase, whereas

Table 3. Potential Foreign Exchange Benefits to Fifty-Seven Developing Countries from 50% Reduction of Protection in OECD Countries

Commodity	Increase in Value of Exports[a]	Percentage Increase in Value
	------ ($million) ------	
Raw sugar	659.0	22.6
Beef and veal	590.8	58.7
Wine	495.2	76.7
Refined sugar	222.1	134.4
Green coffee	136.0	2.7
Maize	82.2	7.5
Cocoa butter oil	61.1	24.1
Wheat	57.9	19.1
Pig meat	53.2	339.7
Tea	49.0	4.8
Molasses	42.6	20.6
Olive oil	38.0	19.7
Groundnut oil	31.6	11.8
Cocoa beans	31.8	2.1
Citrus juice	30.5	35.6
Coconut oil	27.9	8.2
Palm oil	24.7	4.7
Cassava	21.9	3.6
Soy cake	21.6	7.1
Groundnut cake	19.3	7.5
Bananas	18.2	4.2
Barley	16.3	78.2
Coffee extracts, etc.	16.2	8.9
Oranges	15.7	6.5

coffee, cocoa, tea, and bananas combined would amount to less than 10%.

The study by Valdes estimates that even larger benefits could be achieved through increased processing of agricultural raw materials in developing countries before export. If natural rubber, cotton, jute, hides and skins, and timber, at present exported in primary form, underwent intermediate processing in developing countries before export, their gross foreign exchange earnings could at least double from $6.7 billion to $13.5 billion, based on 1975 figures. Moreover, if the processing of rubber and cotton could be undertaken to a second stage of manufacturing, additional export gains of $4.6 billion could be achieved.

Trade liberalization relative to the agricultural products and raw materials (including processing) above may not be sufficient to achieve gains of these magnitudes, nor everything hoped for by LDCs. There is no doubt, however, that restrictions on trade in processed agricultural products, through the use of tariff escalation and nontariff barriers, constitute a major limit to faster growth in the export of these products from developing countries.

While exports of primary commodities will continue to be important for the LDCs, the export of manufactures constitutes a more important element for many poor nations' economic development. Thus, is emphasized the great importance of liberal trade policy as a complement to the rapid growth policies in industrial countries in order to increase economic well-being in the LDCs. In this regard, the results of the Multilateral Trade Negotiations (MTN), concluded in 1979, were disappointing. During the past fifteen years the main center of debate on economic development, as far as trade is concerned, was transferred from the General Agreement on Tariffs and Trade (GATT) to the United Nations Conference on Trade and Development (UNCTAD). Except for preference schemes for manufactured products from LDCs, the Tokyo Round of GATT negotiations were not formulated very differently than those of the Kennedy Round insofar as LDCs were concerned. GATT missed the opportunity during those years to accept principles along the lines which would have accorded free entry to imports from LDCs at an early date as an advance installment, so to speak, of the eventual achievement of the general elimination of tariffs, which in theory should be the logical outcome of future rounds of tariff negotiations.

Unfortunately, the glamor which was attached to the ideas of "preferential treatment" in the quatrennial UNCTAD debates swamped the strength of the free entry and eventual tariff elimination arguments. The "generalized preference schemes" (GSP) which have emerged suffer from many defects. Most schemes are quite substantially circumscribed in scope, and in almost all cases incorporate exceptions and mechanisms of safeguards and control. These exceptions and safeguards are of such nature to lend credence to the charge that they are designed to make sure that competition can be cut off or at least deprived of any encouragement as soon as it threatens to become effective or significant. Such treatment, including time limitations for GSP treatment—such as the ten-year period incorporated in U.S. legislation (U.S. Trade Act of 1974)—also substantiate accusations relative to uncertainty and instability attached to imports from LDCs. In short, LDCs have

much more to gain from multilateral tariff reductions than from maintaining preferential margins, on which UNCTAD efforts have concentrated in recent years. This is because tariff reductions do not involve quantitative limitations on trade and are not reversible, while imports under preferences are subject to quotas and can be revoked on short notice. Developing countries, as implied earlier, need a stable environment in which shifts in the international division of labor so necessary for their rapid economic growth can take place.

In addition to the question of preference margins and free entry, other areas of concern to LDCs were not dealt with adequately in the recently completed trade negotiations. Quantitative restrictions, especially those typified by the Multi-Fiber Arrangement (quota), lead the list. Specific exceptions that industrialized countries have made to the agreed tariff-cutting formula is another area of concern. Developing countries are also apprehensive about the "selectivity clause," which some industrial countries insisted upon being included in the proposed code on safeguards. Developing countries are also worried that the surveillance machinery and sanction powers remain too weak, because it could be the poorer members of the international community who would suffer from violations of the proposed codes of conduct agreed on at Geneva.

Concluding Remarks

Export-cropping critics are worried about many of the right symptoms of economic development, hunger, and nutrition problems. When compared with most organizations which have studied these problems in depth, however, they differ as to causes and cures. The principal benefit derived from literature critical of export cropping is the fact that it has forced the reexamination of methods and plans being used by traditional development organizations. Closer scrutiny has resulted in the correction of errors and better execution of programs.

That type of contribution, while generating interest in food and development problems, contributes little to their basic solution. Export-cropping critics appear to ignore or to turn their backs on empirical evidence that indicates the benefits derived from comparative advantage, trade, and export-led growth. They seem to ignore that along with the benefits of self-sufficiency policies there come substantial costs and risks. That is, variations in domestic food output are going to be high and the resulting price variability will be as vulnerable as that associated with export crops.

Finally, the simplistic and superficial rhetoric which surrounds the self-sufficiency-export controversy often ignores the great diversity of developing country problems. The literature is often not research-oriented, and in addition to its vague generalizations, commits the gross error of extrapolating the experiences of one country to the entire developing world. My suggestion is that the most extreme of the export-cropping critics redirect some of their energies to collecting and analyzing unbiased, representative, empirical data on specific problems for specific countries. I am confident that these data will demonstrate the big gains to be obtained through higher-valued exports and trade rather than reducing present exports by switching resources to agricultural self-sufficiency. It is only at the individual country level that solutions to the export-self-sufficiency controversy can be found.

The Role of Land Reform in Economic Development: Policies and Politics

Alain de Janvry

As the extensive literature on the subject attests, the issue of land reform has been and remains heatedly debated.[1] The latest massive demonstration of interest came with the 1979 World Conference on Agrarian Reform and Rural Development, where representatives of no less than 145 nations and three liberation movements agreed that "equitable distribution and efficient use of land . . . are indispensable for rural development, for the mobilization of human resources, and for increased production for the alleviation of poverty" (FAO). At one time or another, but especially since 1960, virtually every country in the world has passed land reform laws. Yet, the record is far more modest than the premise: (*a*) in spite of decades, if not centuries (Tuma), of land reform activities, landownership remains extremely skewed, concentration of landownership is almost universally increasing, the mass of landless is growing rapidly, and the extent of rural poverty and malnutrition has reached horrendous proportions; and (*b*) in spite of widespread agreement on the need for land reform, there are virtually no significant ongoing land reform programs except under extreme political pressures (revolutionary in El Salvador and postrevolutionary in Nicaragua, Mozambique, and Angola). In several countries, the progressive gains achieved by land reform programs are being either eroded by the forces of economic growth (Mexico, Venezuela, and South Korea) or purposefully canceled by public policies (Chile).

The question I want to explore in this paper is: Why this blatant discrepancy between rhetoric and reality? Or, to put it another way, why is land reform no longer a significant policy issue even though it remains an important political issue in most countries of the world?[2] To answer, we need first to explore, in a positive sense, what has been the nature of different land reforms that occurred in the past; what were their purposes, achievements, and limits. This will be done by developing a typology of land reforms in the third world, because it is essential to distinguish carefully among a wide variety of reforms. Following the approach of political economy, I will do this in the context of modes of production, social class structure, and types of land tenure.

Using this typology, we can then characterize the nature of past land reforms and identify the needed character of future reforms, given the actual state of the agrarian structure. This gives us a basis from which to seek answers to the question as to why land reform appears to be a dead policy issue in most countries today.

By looking at the wide array of rationales and proposals for land reform, we can then identify a number of political stands on the expected role of land reform in the process of economic development. Because land reform is fundamentally a political issue that seeks to achieve or prevent social change, explicitation of the political expectations from reform for different groups permits us to order and clarify the massive number of arguments advanced on the subject.

Types of Land Reform

We need to start first with a few definitions because part of the difficulty with the debate on land reform comes from using different concepts under the same name.

A reform is an institutional innovation pro-

[2] I call policy the institutional changes implemented by the government in power while politics are institutional changes proposed by any social group—dominant or not.

moted by the ruling order in an attempt to overcome economic or political contradictions without changing the dominant social relations. Thus, reform falls short of revolution (where the dominant social relations are changed) and goes beyond mere disregard of economic problems or repression of political demands. While instituted within the ruling order, the origin of reform can, however, rest just as well in the political pressures of the dominated groups as in the initiative of the dominant classes. Land reform, in particular, aims at transforming the agrarian structure. The agrarian structure is characterized by a system of social relations (modes of production and their corresponding social class composition) and a system of land tenure (ownership and usufruct of land and water by farm sizes). Land reforms consequently can change the modes of production in agriculture (themselves dominated by an eventually different mode in society at large which cannot be altered by reforms), the class structure (and, consequently, control of the state by specific classes and their respective access to public goods and services), and the pattern of land tenure.

Use of the concepts of mode of production, social class, and land tenure thus allows us to characterize a variety of states of the agrarian structure. A land reform is then nothing else than an attempt by the government, through public policies, at either inducing a change among states of the agrarian structure or at preventing such a change. A typology of land reforms, consequently, can be usefully constructed as a matrix of changes/no changes among states of the agrarian structure. This is done in table 1 for the thirty-three most important land reforms in the world over the last seventy years.

For our purpose, we can distinguish between three modes of production in agriculture (semifeudal, capitalist, and socialist) and, under capitalism, three landed social classes (capitalist landed elites, farmers, and peasants).[3] This gives us five relevant initial states of the agrarian structure: semifeudal estates controlled by the traditional landed elite with bonded labor (debt peonage, rent in labor services, etc.) and extraeconomic forms of coer-

[3] There are, of course, other modes of production beyond the feudal which are not capitalist or socialist. This includes the Asiatic, Communal, and Lineage modes. Without much loss of generality for the purpose of this paper, I am subsuming all these other modes under the feudal heading.

Table 1. A Typology of Land Reforms

Pre-Land Reform			Post-Land Reform				
		Mode of Production in Whole Society	Capitalist				Socialist
		Mode of Production in Agriculture	Semifeudal	Capitalist			Socialist
		Land Tenure	Semifeudal Estates and Reform Sector	Capitalist Estates and Reform Sector	Capitalist Farms and Reform Sector	Peasant Farms	Socialist Farms
Capitalist	Semifeudal	Semifeudal estates	(1) Mexico, 1917–1934 Taiwan, 1949–1951 Colombia, 1961–1967 Chile, 1962–1967	(2) Bolivia, 1952– Venezuela, 1959– Philippines, 1963–1972 Ecuador, 1964– Peru, 1964–1969 Colombia, 1968–	(3) Mexico, 1934–1940 India, 1950– Guatemala, 1952–1954 Egypt, 1952–1966 Iran, 1962–1967 Chile, 1967–1973	(4) South Korea, 1950– Taiwan, 1951–1963 Iraq, 1958–	(5) China, 1949–1956
Capitalist	Capitalist	Capitalist estates	(6)	(7) Costa Rica, 1962–1976	(8) Peru, 1969–1975 Philippines, 1972–1979	(9)	(10) Cuba, 1959–1963 Algeria, 1961–1971
Capitalist	Capitalist	Capitalist farms	(11) Guatemala, 1954–	(12) Chile, 1973–	(13) Mexico, 1940– Dominican Republic, 1963– Egypt, 1961–	(14)	(15)
Capitalist	Capitalist	Peasant farms	(16)	(17)	(18)	(19)	(20)
Socialist	Socialist	Socialist farms	(21)	(22)	(23)	(24)	(25) Cuba, 1963– China, 1952– Algeria, 1971–1977

cion; capitalist estates controlled by the landed elite-turned-capitalist and using wage labor; capitalist farms and plantations whose owners, the farmers, share in the control of the state with the bourgeoisie-at-large and hire wage labor; peasant farms, ranging from family to subfamily (semiproletarian), where no labor is hired but some may be sold; and socialist farms, either family farms, labor cooperatives, or state farms, imbedded within a socialist mode of production in society at large.

The land reform itself creates a reform sector and transforms or not the agrarian structure into a set of other states. It is important here to distinguish between reform and nonreform sectors, even though most of the literature on land reform considers only the first. The reform sector is the set of farms which is created by expropriation of private lands, distribution of public lands, or colonization of new lands. It is usually organized in the form of family or collective/state farms. The nonreform sector includes the lands retained, subdivided, or sold privately by the former owners. As we will see, most land reforms have sought their economic results in the impact they had on the nonreform sector. After land reform, there are correspondingly five relevant states of the agrarian structure: three where the nonreform sector remains dominant and composed of either semifeudal estates, capitalist estates, or capitalist farms and two where the reform sector is dominant and sometimes exclusive—one under the capitalist mode of production and the other under the socialist mode.

Table 1 classifies thirty-three reforms in twenty countries. A particular country can reenter the matrix more than once if land reform programs are redefined over time, but it must always reenter it in the same state to which it was transformed by the previous land reform. Table 2 provides empirical evidence to support the classification of reforms in table 1 and to identify their respective achievements.

All the diagonal reforms are essentially redistributive reforms in the sense that they either increase the size of the reform sector without changing the nature of the nonreform sector (reform types 1, 7, and 13 in table 1) or redefine the nature of the reform sector (19 and 25). Reform 1 is redistributive within the semifeudal order. Typical examples are the early reforms in Taiwan (1949–51), Colombia (1961–67), and Chile (1962–67), where the main objective was to distribute to peasants empty public lands or lands abandoned by the landed elite without otherwise questioning the continued domination of semifeudal estates in the agrarian structure.

Reforms 2, 3, and 4 aim at liquidating feudal remnants from agriculture and at inducing a transition to capitalism under domination in agriculture of the landed elite (2), farmers (3), or peasants (4). These reforms, directed against feudalism principally during the 1960s, have been both the most prevalent and the most successful in their intents. Reforms that induce a transformation of semifeudal into capitalist estates (2) seek this result by prohibiting bonded labor and rents in labor services (Bolivia, Philippines 1963–72, Ecuador, and Peru 1964–69) and by imposing minimum productivity levels on land use (Venezuela and Colombia). This is obtained by threats of expropriation if these requirements are not met. The purpose of a reform sector, in this case, is more to demonstrate the seriousness of the threats and to satisfy peasants' clamors for land than to increase production. Land reforms (3) induce the reorganization of the nonreform sector into a system of capitalist farms by imposing ceilings on landownership in addition to prohibiting semifeudal social relations. Maximum farm size was thus restricted to 200 irrigated hectares in Mexico (1934–40), 50 in India, 42 in Egypt, 150 in Iran, and 80 in Chile. Here, again, expropriations and creation of a reform sector have mainly the political purpose of stabilization, while the economic gains of the reform are sought in the nonreform sector. The case of Mexico, with its remarkable political stability in spite of massive rural poverty and exceptional growth through the 1950s and 1960s obtained mainly in the nonreform sector, is the clearest illustration of the means and ends of this type of reform. Land reforms (4) are integral reforms in the sense that the nonreform sector is secondary or totally eliminated, and peasants acquire control of the land under the form of family farms (South Korea and Taiwan) or collective farms (Iraq). Taiwan and South Korea demonstrated the economic and political gains of integral reforms where family farms are effectively supported by external institutions that allow them to realize their full production potential.

Once the capitalist order has been established throughout agriculture, transition reforms are passé. The only possible reforms under capitalism in society at large are either shifts among types of agrarian structure (8, 9, and 14) or redistributive reforms within a

Table 2. Characteristics of Land Reform in Twenty Countries

given type of agrarian structure (7, 13, and 19). Historically, the most important type of reform in the first group has been that which transformed the nonreform sector from capitalist estates to capitalist farms (8). Its purpose is evidently to eliminate the landed elite from control of the state and thus achieve a more production-oriented agricultural policy

while creating a more competitive environment in agriculture. This was attempted in Peru by imposing a ceiling on landownership of 50 irrigated hectares on the coast and 30 in the Sierra. In the Philippines, the ceiling was 7 hectares on rice and corn land. With the agrarian structure dominated by capitalist farms, subsequent land reforms can only be redistributive (13) or integral (14). Expansion of the *ejido* sector in Mexico from 1940 to 1977 and expropriation of rice farms in the Dominican Republic are instances of redistributive reforms (13).

All reforms can, of course, give way to counterreforms. Chile thus recreated a landed elite after the military coup of 1973 by abolishing ceilings on landownership, and Guatemala restored semifeudal social relations in agriculture when the Arbenz government was overthrown by foreign armed intervention.

Land reforms that are part of a transition to socialism are evidently more than mere reforms since the mode of production dominant in society at large is transformed—a process which is, by definition, nonreformist (5, 10, 15, and 20). The Chinese land reform was part of a transition from feudal society, while the Cuban and Algerian land reforms originated in agrarian structures dominated by capitalist estates and plantations. Subsequent transformations of the agrarian structure in China, Cuba, and Algeria fall in the category of redistributive reform (25). For lack of space, we concentrate, in the rest of this paper, on land reforms achieved under continued domination of the capitalist order in society at large.

Land Reform as a Policy Issue

During the last seventy years, most land reforms under the capitalist order in society at large have been of either one of two broad types: antifeudal reforms seeking to induce in agriculture a transition to capitalism with the resulting agrarian structure dominated by a capitalist landed elite (reform type 2), a farmer class (3), or a free peasantry (4) and land reforms within capitalist agriculture seeking to create shifts in the dominant rural class from capitalist landed elite to farmers and to peasants (8, 9, and 14) or to amplify the reform sector under domination of either one of these three classes (7, 13, and 19).

Antifeudal Reforms

Reforms against feudal bonds and personalized coercion have originated in peasant rebellions since time immemorial, but they have led to transitions to capitalist agriculture in the third world only during the last fifty years, with the cases of Mexico and Bolivia as outstanding examples. Since the late 1950s, however, with the rise of surplus labor associated with demographic explosion and modernization of many landed estates, organization of rural labor markets with plentiful supplies has created a new rationality to oppose feudalism—this time on an economic instead of a purely political basis: labor relations in agriculture could be transformed from feudal, where labor is a fixed cost, to capitalist where labor becomes a variable cost adjusted to fluctuating weather, market, and technological opportunities. Antifeudal land reforms thus potentially could achieve at the same time equity gains in response to peasant pressures and efficiency gains in response to demands for cheap food originating among urban industrialists and consumers and for increased export earnings originating in the urban-industrial sector. This led to formation, in the 1960s, of broad coalitions of different factions of the bourgeois, peasant, and proletarian classes opposing the feudal landed elites under the banner of expropriation and redistribution of the land. In Latin America, this resulted in the 1961 Punta del Este Charter of the Organization of American States inducing essentially every country of the continent to pass antifeudal land reform laws.

For the dominant interests in this coalition, the objectives of land reform were to be sought in the combination of nonreform and reform sectors. The economic goal was to be obtained by fomenting the development of capitalism in the nonreform sector through a mix of threats of expropriation and inducements to investment (subsidized credit, infrastructure construction, new technological advances, extension services, etc.). The goal of political stabilization was sought by creating a reform sector of a size commensurate with peasant pressures. It is, consequently, only under the most extreme threats of destabilization, such as in Mexico but even more in South Korea and Taiwan, that the reform sector reached major proportions. The success of antifeudal reforms should, consequently, not be assessed in terms of the extensiveness of

expropriations (the publicized explicit goal) but in terms of development of capitalism and political stabilization, with actual expropriations serving only as a means of reaching these goals. In that sense, countries like Colombia, Ecuador, and India had successful antifeudal land reforms without virtually having any in a distributive sense.

In Latin America, the combination of spontaneous development of capitalism and antifeudal land reforms has virtually liquidated feudal remnants and, hence, put an end to this type of reform. The Green Revolution in food production and development of agroexport agriculture, in close connection with international agribusiness, have themselves served as effective surrogates or complements to antifeudal reforms (Arroyo). In most of Asia and the Middle East, similarly, feudal elites have given way to a capitalist elite and a farmer class. In Africa, rapid privatization of the land has also seriously undermined precapitalist forms of land use.

With the end of feudalism, future land reforms must, of necessity, occur within the capitalist order in agriculture. This requires markedly different coalitions and occurs in response to markedly different purposes.

Land Reforms within Capitalist Agriculture

Once agriculture is characterized by capitalist social relations, there are four important reasons why land reform becomes an unlikely policy issue. The first is that the political alliance which must be organized to support land reform will need to be capable of opposing the established capitalist interests in agriculture. This is evidently such a formidable undertaking that it usually will require extreme economic or political circumstances. Opposing the landed elite is difficult because it has strong control of the state apparatus; usually has diversified investments in industry, commerce, and finance that give it economic power beyond agriculture; and is closely allied with foreign capital. Opposing the farmer class is equally difficult since it demands that one fraction of the bourgeoisie oppose another and puts into question the inalienability of property rights. The result is that reforms in capitalist agriculture have only occurred under rather exceptional circumstances, such as government reaction to strong revolutionary pressures (Mexico 1940–77, and the Philippines 1972–75), military interventions in favor of the national bourgeoisie (Peru 1969–75), or external influences (Dominican Republic). Short of this, expropriation of one fraction of the bourgeoisie by another requires full compensation for the former landlords. This, in turn, depends upon availability of a large fiscal surplus or massive foreign aid. This is partly what happened in the Dominican Republic, where the state used the enormous urban and industrial assets confiscated from Trujillo and plentiful foreign aid to compensate fully the expropriated rice farmers. Seen in a historical perspective, however, strong public budgets are unlikely to characterize third world states.

The second reason land reforms in capitalist agriculture are an unlikely policy issue is that the former coincidence of efficiency and equity gains that characterized antifeudal reforms not only may have vanished with the development of capitalism in agriculture but may have given way to a trade-off between these two purposes of reform. With agriculture well advanced on the road to modernization in the context of medium- and large-scale capitalist farms and of a close integration with multinational agribusiness, any drastic land redistribution is likely to nullify past technological achievements and imply short falls in production, at least in the short run. Where the population is increasingly landless and urbanized, the social cost of higher food prices may be more widespread than the welfare gains of land redistribution. This does not mean, of course, that land reforms cannot be managed to avoid efficiency costs: organization of the reform sector on the basis of state or cooperative farms (Peru's sugar farms and the Dominican Republic's rice sector) and establishment of institutions strongly supportive of family farms (Taiwan and South Korea) have demonstrated feasible solutions. However, it does mean that the margin for successful management of reform in terms of production performance is substantially reduced by the very development of capitalism. Seen in this fashion, the Green Revolution and integration of third world agriculture with international agribusiness have both been effective surrogates for antifeudal land reforms and obstacles to subsequent progressive reforms.

A third reason land reforms in capitalist agriculture are unlikely policy issues is that most third world countries have opted for models of economic development where industrial growth is based on expansion of a market for exports or luxury consumption goods and not

principally of a market for wage goods. This implies that progressive income redistribution to create the home market for industry is not essential to avoid underconsumption crises. Like in Lewis' model of the dual economy, where the working class and peasants do not consume the products of the modern sector, income redistribution acts as a break on the rate of economic growth as it lowers the rate of profit. Income redistribution and, hence, land reforms are not economic needs for the system at large in creating the domestic market for the modern sector but political gains of the working class and peasants. For that reason, again, land reforms will only result from strong pressures that can question the existing social order.

A fourth and last difficulty with capitalist land-reform policies is that the bourgeoisie will respond to social pressures for land reform by conceding it for the sake of legitimation of the dominant social relations. Hence, land-reform programs are expected to be as limited as possible while achieving their political purpose. But any program of land reform tends to unleash redistributive expectations and to stimulate broad mobilization of peasants and workers. Limited land reforms are thus an instrument of both expected stabilization and potential destabilization. As Sorj observes for the case of Brazil, this implies that "any attempt at limited agrarian reform will be accompanied by the action of a repressive apparatus and by creation of corporativist bodies intended to keep the reform within the limits of the present structure of accumulation and domination" (p. 31). Faced with both the need to create social support in agriculture and the ambiguities of land reform for that purpose, most governments have turned, since the early 1970s, to the alternate strategy of integrated rural development. The political end is here the same: to create a supportive minority of upper peasants. But the instrument for that purpose need not threaten landownership because technological change becomes a substitute for land redistribution. The example of Colombia is here clear: In 1973, both liberal and conservative parties agreed to put an end to the destabilizing effects of limited land reform resulting, in particular, in continuing land invasions, while launching an ambitious program of integrated rural development with the support of international lending institutions. At the same time, agricultural growth was stimulated by generous public support to the large-scale capitalist sector.

In a postfeudal capitalist order, consequently, it is no surprise that so few land reform policies are being enacted or implemented. Yet, the symptoms of serious agrarian crises remain unabated: food deficits keep on increasing (IFPRI), and rural poverty keeps on worsening (ILO). For this reason, land reform remains an important political issue even if for a variety of different purposes according to contrasted political programs.

Land Reform as a Political Issue

A wide range of arguments has been advanced justifying the role of land reform in economic development, and it is the prevalence of these arguments that keeps land reform an active political issue. Some of these arguments have been advanced on technocratic grounds, while others have been openly couched in ideological terms. Yet, all land reform programs fit within some global view of the role of agriculture and peasants in economic development. These can be regrouped under four alternative political programs, each of which proposes land reform for sharply contrasted economic and political purposes.

Land Reform for Social Status Quo: The Conservative Model

With capitalism well entrenched in agriculture and the performance of agriculture fundamentally determined by market incentives and public and supporting institutions (infrastructure, technology, credit, etc.), the conservative model allows for land reform only as a minimal concession for political stabilization. Creation of a reform sector is used to defuse social tensions when pressure on the land (land invasions, etc.) or revolutionary threats are excessive. It does this by allowing some vertical mobility to peasants and by creating a buffer minority of privileged peasants in the reform sector whose economic success is tied to the interests of capitalist farming and to continued patronage of the state but whose ideological allegiance is still with peasants. As such, they tend to become the political representatives of the peasantry at large and strong advocates of the social status quo that benefits them so exclusively. Land reform is here purely legitimizing of the dominant social relations. It only becomes an active political issue when this legitimacy is being questioned. It is, consequently, only in the following three

positions that land reform is an integral component of political programs.

Land Reform for National Bourgeois Revolution: The Liberal Model

For as long as feudal elements dominated agriculture, national liberal forces were directed at promoting antifeudal land reforms. With the omnipresence of capitalism, the same forces identify their targets in terms of opposing blatant external dependency relations and in terms of redefining the social and geographical location of the market for the modern sector in wage earnings as opposed to profits, rents, and exports. Both creation of a class of farmers instead of a capitalist landed elite (land reform type 8) and redistribution of land to peasants (7, 9, 13, and 14) are seen as ways of expanding the domestic market for wage goods. Since farmers and peasants are oriented more toward producing basic wage foods than the landed elite, which is principally involved in the production of agroexports, these land reforms also are proposed as mechanisms for reducing the bias against food and alleviating the food crisis. Finally, by reducing inequality, they are seen as essential to creating the economic basis needed for more democratic forms of government. In Brazil today, for example, land reform is an important rallying point for dispersed forces struggling for a return to civilian democracy.

Land Reform to Give the Land to the Peasants: The Populist Model

This position usually is argued in technocratic terms by pointing at the superior social efficiency of small farms and peasants under conditions of surplus labor: smaller farms produce more per acre than larger ones and reach a higher total factor productivity when labor and capital are valued at their social opportunity cost, which is virtually zero on small farms. Integral land reforms (types 9 and 14) to create a free peasantry are, thus, advocated since peasants' higher levels of (Chayanovian) self-exploitation lead them to deliver cheaper food on the market than capitalist farming, at least for as long as the productivity of labor is nearly equal on small and large farms (Dorner and Kanel, Lipton). As Berry and Cline put it, "land redistribution should therefore be expected to raise total output by combining underused labor from small farms and the landless work force with underused land on large farms. Nor is there likely to be a sacrifice of potential efficiency from land redistribution, because it is unlikely that there will be significant economies of scale for actual farming operations" (p. 29). Integral land reforms are, in turn, the preconditions for any meaningful effort at rural development (Wortman and Cummings). Efficiency gains are, of course, also accompanied by equity gains with the result that the populist vision of land reform offers the same logical panacea for capitalism as antifeudal reforms did.

Land Reform for Social Change: The Radical Model

A radical interpretation of the agrarian crisis in the third world essentially concludes that (*a*) Once feudalism is gone, the problems of agriculture are essentially nonagrarian as they reflect the contradictions of the global model of economic development pursued—characterized by its export and luxury orientation and by strong relations of external dependency. This, in turn, leads to a bias against food production (cheap food policies) and in favor of agroexports (comparative advantage theory). And (*b*) peasants are rapidly being dispossessed of their status as producers and transformed into a reserve of cheap semiproletarian labor.

Since resolution of the agrarian crisis consequently hinges upon broad social changes in the economy at large, land reform per se is necessary for economic development but certainly is insufficient. Yet, land reform need not wait for broader social changes to occur. The promotion of land reform itself is seen as an important instrument of social change, as a rallying cause to foment the organization of peasants and workers and the emergence of new ideas. Land reform is thus a process that is to be carried on by and not for the peasants and which is completed only with the restructure of the global social system.

Conclusion

Transformation of the agrarian structure is today more dependent upon the forces of capitalist development and, in particular, on the industrialization of commercial agriculture and the proletarianization of peasants than upon the application of land-reform policies. Solutions to food and balance of payment def-

icits are sought in medium- and large-scale capitalist farms closely integrated with international agribusiness. Peasants' demands for better living conditions are either neglected and left to the uncertainties of domestic and international migration or severely repressed. Yet, it is abundantly clear that the crises of food production and rural poverty are, if anything, worsening under the current development model. Thus, even if land reform is dead as a policy issue, it remains a key ingredient of any meaningful political program of economic development, be it of liberal, populist, or radical slant.

The Role of the Multinational Corporation: Discussion

Terutomo Ozawa

In his thought-provoking paper, Goldberg points out that national food systems have become more and more internationalized and intertwined with each other, and that this interdependent global food system has gravitated, on the whole, toward North America, which is "the only significant surplus grain-producing area in the world." He foresees a further expansion of this globally integrated food system as a result of population pressure and an ever-rising need for food, especially on the part of developing countries, whose agricultural sector is still largely subsistent and noncommercial, with an extremely low level of productivity. Against this backdrop, Goldberg then explains how new opportunities have been and will continue to be created for key operators in a vertical food system to cross national boundaries and operate in foreign markets, that is, to become multinational.

As we all know, multinational corporations generally are regarded as a mixed bag of malevolent and benevolent forces or as institutions with psychotic behavioral patterns somewhat like those of Dr. Jekyll and Mr. Hyde. At one extreme, for example, Marxists consider multinationals nothing but a devilish instrument of capitalistic exploitation and neo-imperialism. At the other extreme, neoclassical liberals—and managers of big business in general—consider multinationals a dynamic engine of economic development and coprosperity, a savior of mankind from economic inefficiency and backwardness, and lament that its messianic mission is hampered only by the parochial interests of sovereign states. Both views have some validity, depending on the circumstances under which multinationals are allowed to operate.

The multinational corporation is by nature monopolistic in terms not only of the size of its operation but also of the superior knowledge it generates and tries to possess exclusively, and it is efficient at exploiting such knowledge; but its monopolistic power is an inevitable cause of inequity when it operates in developing countries where, in general, countervailing power either does not exist or if it does exist, is not judiciously exercised.

Goldberg describes very well the "Dr. Jekyll" side of multinationals by citing several "socially useful" cases. All these are "good citizen" citations, as they are judged, in his opinion, to be contributing to the agribusiness needs of the developing host countries. These examples of "socially useful" operations are indeed encouraging. Yet, I am still left uncomfortable about the "Mr. Hyde" side of multinationals. Goldberg does give us a warning of the power of multinationals, but he does so only implicitly by quoting a statement made by Galbraith. Goldberg says nothing about our recent experiences with the abuse of such power by multinationals. Perhaps we are too familiar with it to need to be reminded of the tragedies that occurred recently when infants in developing countries were fed baby formula marketed on a *caveat emptor* basis by multinationals.

In a section on Japanese trading companies, Goldberg advances a generalization: "In essence, commodity trading firms do not just buy cheap and sell dear, but rather recognize that they are an integral part of the food policies of the countries in which they operate and help, in cooperation with the government, to improve the efficient handling of the commodity. . . ." Here he neglects to remind us that only in the recent past Japan's trading companies have been castigated at home not only once but repeatedly for their flagrant market-cornering activities in stocks, land, wool, cotton, soybeans, timber, and other primary commodities. Neither does he mention the fact that during the Great Grain Robbery of 1972, when the Soviet Union purchased an unpredictably large quantity of wheat, Amer-

---

Terutoma Ozawa is a professor of economics, Colorado State University.

ican grain dealers kept their operations in strict secrecy, leaving the American farmers and public in the dark—the result being that the United States played into the hands of the Soviet Union. This incident led to a new federal regulation requiring U.S. companies to report to the Department of Agriculture their sales contracts involving U.S. grain. The end result, however, was that the American grain dealers became more multinational in their activities for the purpose of evading the law, because the contracts made by their overseas affiliates were not subject to the reporting requirement.

It is equally important to remember that in the context of prevailing political conditions in many developing countries, "cooperation with the government" (a point Goldberg emphasized) does not necessarily mean that the poor masses can share the benefits from the cooperation rendered by the multinationals. Indeed, the so-called *dependencia* theory of direct foreign investment has lately shifted its emphasis from the exploitation of developing host economies by multinationals to the exploitation of the poor masses by a coalition of host government officials, landlords, elite local business interests, and multinationals. Nor does the "commercialization" of the subsistent sector advocated by Goldberg necessarily lead to an improvement in the welfare of either subsistent producers or local consumers. It is well known that the enclave type of commercial farming not infrequently drives away powerless "small farmers" from even subsistence itself.

Goldberg is no doubt quite aware of all these malevolent externalities caused by multinationals, but is intentionally concentrating on "socially useful" cases. Yet it is not certain how widespread and how significant those benevolent activities are in relation to the totality of multinationals' engagement in global agribusiness. Detractors can easily marshal an equal or even larger amount of evidence that indicates how detrimental the impact of multinational agribusiness is on the basic needs of developing economies. The best argument Goldberg can make, then, is that those "socially useful" cases do exist and that the light from at least a few candles, however faint and flickering they may be, is better than the total darkness of the current "storm over the multinationals" (Vernon).

Goldberg uses as his theoretical frame of reference only the product-cycle theory of foreign direct investment—perhaps because it is the theory advanced by his colleagues at the Harvard Business School. But his use of only this limited model, originally developed for the manufacturing sector, is clearly inadequate—and, moreover, inappropriate, particularly for the specific examples he uses in illustration. As is well known, the product cycle theory was developed to explain the specific historical experiences of American manufacturers during the 1950s and early 1960s when U.S. industry was undisputably the world's dominant innovator of products and processes. These innovations, the theory posits, have served as competitive assets for American manufacturers to exploit, first through trade and later through overseas investment.

Given the nature of the product-cycle theory, one can easily see that the examples of Japan's Zen Noh and other agricultural cooperatives and the Thai-Japanese corn agreements, for instance, cited in Goldberg's paper do not fit into the theory. He should have used, instead, the market-internalization theory of the firm, a theory originally developed by Coase and recently applied to the analysis of multinational business by Buckley and Casson. In essence, the internalization theory explains why a firm or an organization (which is a consciously coordinated entity) takes over the market (which is unconsciously coordinated by the price mechanism). We know that the main function of farmers' cooperatives, for example, is to reduce the risk of dependence on the vagaries of the market and to gain some control over prices and total supply through coordination arrangements—namely, to internalize, if not totally then partially, the market. The *raison d'être* of Zen Noh and other agricultural cooperatives is nothing but this internalization of the market.

In fact, once the concept of multinationalism is defined as a process of internalization across national borders, it fits very nicely Goldberg's own innovative notion of a commodity systems approach:

> An agribusiness commodity system encompasses the participants involved in the production, processing, and marketing of a single farm product. It includes farm suppliers, farmers, storage operators, processors, wholesalers, and retailers involved in a commodity flow from initial inputs to the final consumer. It also includes institutions which affect and coordinate the successive stages of a commodity flow such as the government, futures markets, and trade associations. These coordinating institutions and ar-

> rangements play an especially important role in agribusiness commodity systems because of the unique agronomic characteristics of the industries. The phenomenon of seasonal production of crops, combined with year-round consumption of food products, results almost inevitably in serious imbalances between supply and demand. (Goldberg, p. i)

His strong advocacy of this systems approach is nothing but a call for conscious coordination of economic activities by key operators in a vertical food system in order to control, *inter alia*, the "inevitable imbalances between supply and demand" brought about by the market. It is a call for internalization of those market segments whose transactions are not efficiently performed by the price mechanism. The activities of multinational organizations illustrated by Goldberg are good examples of this systems-focused process of market internalization.

The Role of Export Cropping in Less Developed Countries: Discussion

Malcolm D. Bale

The paper by Hillman is a quite well-balanced representation of the issues with respect to the role of agricultural exports in development. It is a concise restatement of existing problems containing little policy advice for the future. It may be a useful survey piece to the nonspecialist, but there is little new for development or trade economists. In this respect the title is misleading. I kept waiting for the paper to focus on export cropping. Of course, it really does not. A more appropriate title would be "Export Orientation versus Self-sufficiency in the Agriculture of Developing Countries: A Survey of Issues." The paper is more notable for what it does not say than for what it says. Accordingly, most of my comments will focus on these aspects.

The main criticism of the paper is that it is a survey of what has happened and of past issues. It is long on diagnosis and short on prescription. Critical issues in agricultural development and questions that confront economists are: what is the correct valuation of agricultural output, and what advice can we provide developing countries? These are difficult questions to answer. Hillman seems to favor agricultural export-led policies. But the preconditions for this to be effective, as he states, are that growth in industrialized countries must continue at a rapid pace through the 1980s and that market access must be increased. Neither of these preconditions are projected to obtain in the 1980s. Economic growth in industrialized countries throughout the 1980s is projected to fall below the sluggish levels of the 1970s (see World Bank), and many observers in their most optimistic moments see at best a constant level of protection for agriculture during the 1980s. Thus, the question arises as to how agricultural export-oriented policies possibly could help developing countries.

One possible alternative for developing countries is to look toward increased inter-developing country trade. Preliminary work by a colleague of mine, Duncan, indicates that over the period 1963–76, the share of developing country trade to other developing countries rose. More impressive than market diversification is the changed product diversity of developing country exports. Manufactures now (1976) account for 45% of developing country exports; 22% of exports are of processed products, and only 32% of exports are primary products. This is a dramatic change from 1962, where the shares were 19%, 25%, and 56%, respectively. Within developing countries, the middle and high income countries have performed the best in terms of growth in product and market diversification. Manufactured exports from Latin America, for example, have trebled over the period, most of this increased trade going to other developing countries. The evidence from this and other work (Hughes, Stewart) seems to converge on the result that increased inter-developing country trade is occurring in a Balassa "Stages" manner, with higher income developing countries increasingly trading with lower income developing countries. Thus, it is no longer useful to classify the third world as a homogenous group as is done by Hillman. In short, there is a spectrum of development stages such that across-the-board developing-country recommendations become largely meaningless.

At several points in the paper, the issue of instability and food security arise. With respect to agriculture, the issue for developing countries is the same whether they are agricultural exporters or importers. That is, how can the inevitable problem of fluctuating export-receipts (for exporters) or foreign exchange requirements (for importers) be best

Malcolm D. Bale is an economist in the Economic Analysis and Projections Department, Development Policy Staff, World Bank.

The author acknowledges insightful discussions on this topic with Ron Duncan, Oli Havrylyshyn, Clifford Lewis, and Ernst Lutz. This notwithstanding, he makes the following formal disclaimer: The views and interpretations in this paper are those of the author and should not be attributed to the World Bank, to its affiliated organizations, or to any individual acting in their behalf.

cushioned? There have been several recent approaches to solving this problem not mentioned in the Hillman paper. There is the scheme based on insurance principles, where concerned importing countries set aside foreign exchange during times of low food prices to use in times of high food prices (Konandreas, Huddleston, Ramangkura). There is the International Monetary Funds (IMF) compensatory financing facility, where a country in balance-of-payments difficulties may draw up to 100% of its quota, if exports fall below trend. Also the European Community's "Stabex" scheme under the Lomé Conventions offers grants and interest-free loans to the associated developing countries if export earnings fall. Finally, the most recent stabilization scheme of large potential importance to developing countries is the recently agreed-upon "Common Fund" for agricultural commodities. Its establishment is a significant achievement because it is the first successful effort to bring about changes under the "New International Economic Order" through negotiations between developed and developing countries. The Fund will be the first international financial institution to be established since the Bretton Woods institutions.

The basic rationale underlying the proposal for a Common Fund was that its establishment would facilitate the formation of commodity agreements by providing finance for buffer stocks. The pooling of buffer funds across several commodities whose price swings were not in phase would be an efficient method of gaining leverage in commodity markets. That is, receipts from buffer stock sales of a commodity during its high price swing could be used to finance the purchase of stocks of another commodity whose price at that time was in a trough.

While there is a high degree of enthusiasm over the potential of the Common Fund from developing countries, whether it can achieve its goals remains to be seen. The assurance of funding for buffer stocks may not be sufficient to bring commodity negotiations to a successful conclusion. In the past, negotiations have foundered not over the issue of a buffer stock but over the question of the release-and-acquisition-prices of the buffer.

Hillman states that the agricultural sector in developing countries is taxed and subsidized. The weight of evidence of many case studies indicates that there is little subsidization but a considerable degree of taxing in agriculture in developing countries. Taxes are a serious problem severely skewing the terms of trade of agriculture in developing countries and hindering exports. While we can find a few examples of subsidies (usually on inputs), they are isolated and unimportant relative to the various taxes, levies, and price controls on agriculture. (See Peterson, Lutz and Scandizzo, Bale and Lutz, and case studies cited by the latter.)

As has been noted by Schultz and restated here, "the principal controversy surrounding food security relates primarily to man's policy role, not to the limitations of man and nature to produce enough food" (p. 16). I strongly concur with the position that various interventions in the agricultural complex have a negative effect on output. Hillman follows this by correctly pointing out that institutional changes have tended to reduce the prospect of food insecurity over the years and cites such changes as communications and transportation, enlightened attitudes, and tradable food reserves held by grain-exporting countries.

While these tendencies are correct, the world's food system is ill-equipped to handle major shocks. We are all familiar with the capacity constraint of the St. Lawrence Seaway, the bottleneck of lock 26 on the Mississippi, and the virtual closedown of the Port of Portland due to sedimentation. This infrastructure simply would not allow sudden increased shipments of stored grains in response to a foreign shortage. Further, there are infrastructure problems in importing countries. The vastness of a country such as India combined with insufficient communication and transportation make it extremely difficult for parastatals to understand, let alone manage and coordinate, the food procurement and distribution system. In addition, reports of silting-up of irrigation systems at a rate greater than the rate of development of new irrigation systems, due to an imbalance of investment in new structures over maintenance, serve to emphasize the delicate balance within which the global food distribution system operates.

I find myself in substantial agreement with the discussion on the importance of freer trade to developing countries, but I think that it is incorrect to imply that the gains to developing countries of the Tokyo Round were negligible. The value of import concessions by the European Community (EC) and eight industrial countries to developing countries has been estimated at an annual level of $12 billion in

agriculture and $28 billion in industry (GATT 1980). In addition to these pecuniary gains, developing countries stand to benefit (along with the rest of the world) from the reformation of the trading codes.

If, as Hillman states, developing countries are disappointed in the results of the Tokyo Round, it is relevant to ask why their expectations were not achieved. The reasons are important, I think, because they are frequently overlooked by economists. First, few developing countries are members of GATT and therefore few participated in the multilateral trade negotiations (MTN). Second, and more important, trade negotiations are complex and specific undertakings. Industrialized countries, when embarking on them, establish priorities as to which commodities they wish to negotiate greater market access and which commodities they are prepared to "trade-away" in return. Before going to the negotiating table, developed countries have defined their individual particular interests. Developing countries tend not to do this but rather come to the table with broad and sweeping catch-phrases, such as "greater market access," or "special differential concessions." They do not focus on narrow commodity-specific issues because, in general, they do not have the large intellectual pool of academics and support-staff backing them up with analyses of the various scenarios. When trade negotiations get down to serious bargaining at the commodity level, they normally involve only half a dozen individuals representing countries that have a particular interest in that issue. Thus, if developing countries have not examined and defined their positions along with working details of them, they tend to be left on the periphery of the negotiations. If they wish to influence the course of negotiations, it is necessary for them to have well-documented, specific cases.

I will close by supporting Hillman's view that when comparing export-oriented versus self-sufficiency policies, the weight of evidence supports strategies that encourage further exports, although, as Hillman emphasizes, there are exceptions to this. Yet, I believe that our profession must go beyond giving such broad advice, especially in view of the sluggish growth prospects in the industrialized world. Rather, we can perform a greater service to developing countries by formulating precise proposals focusing attention on alleviating specific bottlenecks in their agricultural sector.

The Role of Land Reform in Economic Development: Policies and Politics: Discussion

Daniel W. Bromley

There are several important points made by de Janvry: one relates to his taxonomy of land reforms by country and over time, another is to be found in his four reasons land reform will not be an important issue on the economist's research agenda in the coming decade. With respect to his taxonomy, de Janvry claims that it permits the identification of the needed characteristics of future reforms, given the actual state of existing agrarian structures. He then argues that this gives us a basis from which to seek answers to the question about why land reform appears to be a dead policy issue in most countries. I have four concerns with respect to his treatment of the land reform issue and will now turn to a brief discussion of each.

My first concern is that the four reasons he offers for why land reform is a dead policy issue do not follow uniquely from his analysis but could be derived quite independently. De Janvry offers the following reasons: (*a*) the political alliance for land reform must be capable of opposing an established capitalist class in agriculture; (*b*) all efficiency gains from land reform have virtually been exhausted; (*c*) domestic demand is no longer important as a macro consideration since the industrial sectors are primarily export oriented; and (*d*) the ruling class will only give in grudgingly and in small doses. I see little unique about his paradigm or his taxonomy which produce these findings. To put it differently, it is possible to arrive at these conclusions quite outside of his analysis.

My second concern is that the above list of reasons for the demise of land reform as a policy issue, while rather reasonable in spite of my contention that they do not follow from his analysis, misses one very important consideration. A plethora of changes have occured in the developing economies which, in combination, drive down the economic role of land to the point that in some instances access to—or control over—land may be quite irrelevant. Perhaps this is implicit in his second item on the above list, but its importance warrants special mention.

The advent of high-yielding varieties, increased reliance on chemical pesticides and fertilizers, control over irrigation water, and the multitude of ways in which urban dominated agricultural policy can countermand any nominal gains from better land use opportunities all combine to render—in many instances—land ownership quite irrelevant. There are so many factors which impinge upon the economic environment of a newly landed peasant that the legal and/or economic relations of that person to the land resource may be quite beside the point. Land cannot be considered important in either a policy or a political context when it is often so irrelevant in the ultimate reckoning of a peasant's economic position.

My third concern is that his paradigm, which concentrates on modes of production and class relations, is overly rigid and not terribly helpful analytically. For instance, he says that a reform is an institutional innovation promoted [permitted?] by the ruling order to overcome economic and/or political contradictions without changing the dominant social relations. However, if the agricultural population is transformed from one of 10% landowners and 90% wage laborers/tenants to one of 75% landowners and 25% wage laborers/tenants, it is hard for me to see how the dominant social relations have not been seriously altered. The fact that the nonagricultural sector remains capitalist, along with the agricultural sector, may make it seem that social relations have not changed much, but this is

---

Daniel W. Bromley is a professor, Department of Agricultural Economics, University of Wisconsin.

an artifact of a model that sees social relations as derivative of modes of production writ large. It is the old capitalist/socialist dichotomy, and here it seems to miss very important changes in social relations even in the absence of a transition from capitalist to socialist modes.

To de Janvry, revolution is the only thing which will alter social relations, and here he would mean a transition from feudal to capitalist, or feudal to socialist, or capitalist to socialist. This sort of rigid dichotomy does not seem very helpful analytically, especially when it leads us to conclude that dominant social relations have not been altered by a massive redistribution of land within the capitalist mode. When this new economic opportunity is created for the formerly landless, few could deny that sweeping changes have occurred in the social relations governing rural life.

My fourth and final point concerns de Janvry's use of the term "land tenure." He says that land reform changes the modes of production, the associated class structure, and the pattern of land tenure. I may be missing something here, but I consider it more helpful to say that land reform alters four aspects of the man/land interface: namely, (*a*) who controls land; (*b*) who may use land; (*c*) who reaps the benefits of land use; and (*d*) who bears the costs of land use. Once said, we then can explore the nature and extent of changes in these four factors, and we might conclude that the dominant mode of production has been changed, and that this will then hold important implications for social relations. Simply put, I question his causal chain which runs from modes of production to class structure to land tenure.

In closing, let me emphasize that in spite of my concerns, I found the paper to be useful, informative, and an important new perspective on a topic which—as he indicated—will remain an important political issue. The symbolic value of land will remain prominent, even as its economic value may be allowed to decline.

Books Reviewed

Boris, Constance M., and John V. Krutilla. *Water Rights and Energy Development in the Yellowstone River Basin: An Integrated Analysis.* Baltimore, Md.: Johns Hopkins University Press for Resources for the Future, 1980, xiv + 278 pp., $25.00.

The staff at Resources for the Future has again accomplished the difficult task of producing a book that has substantial relevance for both policy makers and academicians. Boris and Krutilla's analysis of water use alternatives in the Yellowstone basin, with emphasis on the issue of water availability for energy development, constitutes a useful treatment of an important policy issue.

The approach used by the authors consists essentially of four parts: (*a*) a detailed specification of legal and institutional constraints to water development and use; (*b*) an assessment of competing water use demands, including demands for coal mining, processing and transportation, electrical generation, irrigation, municipal use, industrial use and instream flow reservations; (*c*) a discussion of the interrelationships between water quality and water quantity; and (*d*) development of a refined hydrologic simulator used to specify water availability under a variety of water use scenarios. Their analysis is limited to surface water considerations and does not consider the economics of alternative uses.

One particularly noteworthy point which runs throughout the book is that the authors remain realistic and never fall prey to the god of efficiency or to the narcotic of idealism. Most analyses of water use alternatives with which this reviewer is familiar use some form of economic efficiency calculus to predict what will and/or should happen under selected scenarios, with an often times consequent loss in realism and policy usefulness. In contrast, the authors recognize the relevance of economic considerations, but are willing to acknowledge and accept the predominant role of political criteria in water allocation. They then proceed to follow this acknowledgement with a very detailed and complete assessment of the legal-institutional environment in the Yellowstone basin. Indeed, their treatment of existing water rights, including the federal-reserved water rights issue, constitutes an excellent example of how to integrate effectively institutional and engineering considerations in policy analyses.

The single major deficiency in the analysis is the author's failure to consider adequately the potential significance of ground water as an alternative source of supply. The authors note that substantial ground water supplies are physically available from the Madison formation, but do not explore extensively to what extent ground water could constitute an economically feasible source of water for some uses. The absence of information about this issue, although admittedly outside the scope of their study, makes it hazardous to draw definitive conclusions about the potential limits or trade-offs associated with energy developments in the Yellowstone basin.

In general, the book is extremely readable and should be easily understood by water or energy specialists and generalists alike. In view of the significance of the Yellowstone basin to the national potential for coal development, the book should be must reading for the full range of people engaged in water and energy policy formulation both within and outside the region. The book also can serve as a useful reference source for background information about a wide range of related issues, including everything from Indian water rights to the amount of water required for a coal slurry pipeline. Last but not least, scholars engaged in similar work will find the book an excellent example of how to approach complex policy issues in a manner that is simultaneously useful and methodologically defensible.

Raymond J. Supalla
University of Nebraska

Campbell, Keith O., *Food for the Future,* Lincoln and London: University of Nebraska Press, 1979, x + 178 pp., $12.50.

Following a brief discussion of the trends in food demand and the current state of world agriculture, the author addresses the issues associated with expansions of world food supplies. The role of agricultural research and technological change receives a great deal of attention. Other factors important for the future food supply, e.g., resource constraints, energy supply, rural institutions and infrastructure, and government policy are also treated in considerable detail.

Considering the period up to year 2000, the author firmly believes that world food supplies can be expanded to meet increasing demands. While he rejects predictions that we are headed towards catastrophic food shortages on a global level, he concludes that governments must place very high priority on efforts to expand food production. Research and technological change is considered by the author to be the key to rapid growth in food supplies. The need for expanded public investment in agricultural research is emphasized. It is felt that current underinvestment in such research may continue into the future because of the weak lobbying position of the agricultural sector. The need for

public policy to facilitate technological change and expansions in food production is also emphasized, and it is argued that appropriate economic policies are much more important than expanded advisory services to farmers. A set of such policy areas is presented and a number of existing policy measures biased against agriculture and food production are discussed. The author does not feel that resource constraints are likely to impose serious limitations on efforts to expand food production during the next twenty years and he argues effectively and convincingly against the use of energy input/output ratios instead of economic relationships as a guide for resource allocation in agriculture.

The book is focused on the supply side of the food problem and does not promise to treat the demand side. However, such a focus does not justify the implicit view that rapid expansions of the food supply should be considered as a goal of a higher order and not a means to improve the well-being of people. The author seems to argue for rapid expansions in food supplies for its own sake and sees little or no reason to consider side effects when planning the strategy for obtaining such expansions.

Poverty-oriented development strategies, redistribution of productive assets, e.g., land reforms, and programs to alleviate malnutrition and starvation caused by lack of purchasing power are dismissed if they in any way conflict with the goal of expanding food supplies. The author seems to think that such conflicts between growth and equity are the rule rather than the exception. Efforts such as subsidies and price support, which encourage low income farmers to stay on the farm and, thus, slow down rural to urban migration, are hindering "progress" and should be avoided according to the author. Even the "family farm" falls by the wayside if a different tenure system is more efficient in expanding food supplies.

Although the author provides no viable alternative for the rural poor, he suggests that we recognize the "antiprogressive" nature of poverty-oriented rural development programs such as those promoted in developing countries by the World Bank and the U.S. government.

To summarize, Campbell provides us with an excellent analysis of the principal factors influencing the future food supply. The message is clear: expanded public investment in agricultural research and technological change combined with investment in rural infrastructure and public policy to facilitate rapid food supply expansions are essential to meet future food demands. With such investments and policy, resource constraints, including energy scarcity, are not likely to be of major concern in assuring the required supply expansions.

While Campbell recognizes the existence of severe poverty, malnutrition, and starvation in many developing countries, he suggests that these problems be dealt with separately "as part of a more general attack on the problem of poverty" (p. 146). Yet he dismisses poverty-oriented rural development programs as inappropriate and undesired by many developing countries. However, in a world where a large proportion of the absolute poor depends on agriculture for their livelihood and where food expenditures by the poor account for a large share of total incomes, an agricultural development strategy that ignores distributional effects is grossly inappropriate. Growth and equity goals must be integrated into the strategy—not dealt with separately. Poverty problems in high income countries such as Australia and most of Western Europe may be dealt with through separate welfare programs. But a viable solution to the poverty in most developing countries can only be found within an integrated growth/equity development strategy.

Goldberg, Ray A., and Richard C. McGinity. *Agribusiness Management for Developing Countries: Southeast Asian Corn System and American and Japanese Trends Affecting It.* Cambridge, Mass.: Ballinger Publishing Co., 1979, xxv + 643 pp., $17.50.

The authors have undertaken the monumental task of comparing and contrasting the organization of production, marketing, and consumption of corn in the United States, Japan, Indonesia, Thailand, and the Philippines. From these diverse economic systems the authors attempt to draw generalizations as a guide for private and public decision makers for "developing an effective food system." Failure to accomplish this goal is more a reflection of the complexity of the task than on the capabilities of the authors.

The focus of the book is agribusiness, defined to encompass a complete vertical cross-section of the corn industry from geneticists to consumers in each country. The firms and agencies comprising these systems are described in detail, and differences in scale and structure are amply illustrated with 269 tables and 50 figures. With only 149 pages of text, the book relies heavily on the twenty-one case studies (358 pages) to provide insight into the decision-making processes of producers, processers, cooperatives, and government agencies in each country.

Although the tables and diagrams provide a valuable resource, the authors fail to utilize their full potential. For example, figure 5–11 and 6–1 are identical, an entire page is allocated to each, but they are scarcely mentioned in the text. These complex flow diagrams would benefit from additional explanation and interpretation.

The description of the market structure in each country facilitates comparisons among the contrasting economic systems. However, the lack of an

analytic model within which the selected structural variables are related to performance creates difficulty for the reader in sorting out desirable policy actions. Industry concentration ratios within the corn-marketing sectors are often related to decreased competition and abuse of market power. Yet no guidelines are offered as to appropriate firm numbers. In the Philippines, 24,000 wholesalers are not sufficient to ensure competition in purchases from farmers; while the Thailand corn industry is described as very competitive, with five firms owning all port facilities. It appears that the word "competition" is sometimes used as a behavioral term and sometimes as a structural variable. Differing degrees of competitive structure are not identified as the description moves vertically through each segment of the system. Identification of the structure and performance variables and relationships would add some analytical depth and perhaps facilitate drawing generalizations from the detail contained in the case studies.

The human interest details add a sparkle to the lengthy case studies, but the central theme is sometimes obscured as you worry with Mr. Pullin about the lease that expires in August and whether or not he should purchase those extra feeder pigs. The information about the family from the Philippines living in a nipa-roofed hut with a secondhand sewing machine also provides an interesting background for understanding the small farmer's role in the Philippine corn system, but the relevant information could have been condensed significantly.

A few errors occasionally creep into the descriptive material. For example, "milling intransit rates in the U.S. ceased to exist by the early 1970's" (they are still in use by many grain and soybean processors); "the typical covered grain hopper car carries 60 tons of corn" (70% of the current covered hopper fleet is in 100-ton hoppers); "a bushel of corn weighs about 56 pounds" (it weighs exactly 56 pounds, by definition). Despite several of these minor errors, and a number of typographical errors that could have benefited from closer editing, the book amply demonstrates the role of economic incentives in stimulating production response and the importance of the vertical system and coordinating mechanisms to development of an economically viable commercial corn sector.

The authors' description of the purchases of U.S. country elevators by international grain firms raises many interesting questions about causes and effects. Unfortunately, most of these questions are left unanswered as the section digresses into the issue of foreign ownership of farmland—of questionable relevance since there is no evidence that farm ownership is related to the vertical integration of the grain firms.

In the concluding chapter the authors face up to the limitations of the case study approach in meeting their objectives. In summarizing all of the experiences, they conclude that no pattern for success or failure has developed; a program that worked in one region failed completely in another. The book succeeds in illustrating two important principles that I would have liked to see given more emphasis. The first is that policy changes related to commodities must take into account the entire vertical system and its interfaces. The second principle is that when the economic incentives are present, individual decision makers will develop the production and infrastructure necessary so long as government policies do not interfere. Although the authors were unsuccessful in constructing a blueprint for developing an economically viable corn industry, their identification of the essential vertical relationships within and between countries provides useful insights for policy makers in developing economies. Students of grain marketing and economic development alike will benefit from these insights and will enjoy the detailed description providing a better understanding of the corn systems around the world.

Helmers, F.L.C.H. *Project Planning and Income Distribution*. Boston: Martinus Nijhoff Publishing Co., 1979, 295 pp., price unknown.

The focus of this book is on project analysis and selection in developing countries. It consists of two parts—one devoted to conventional project-planning criteria and the other to income distribution aspects. The first part is a thorough critical survey of the state of the arts with reference to such issues as the valuation of project benefits and costs, the analytics (e.g., optimal scale and timing) of project planning and project ranking. The second part is the real "raison d'être" of the volume. It covers such difficult questions as social welfare and benefit-cost analysis and intertemporal and interpersonal income distribution aspects. Recognition and adoption of poverty alleviation as a major policy objective leads to the major theme of the book, i.e., that income distribution objectives have to be incorporated into project analysis.

The opportunity cost doctrine is accepted in part 1 as a starting point for the measurement of costs of production. A whole chapter (3) is devoted to presenting various methods which have been proposed to estimate the shadow prices of different inputs. The discussion of how linkage effects among projects, externalities and macroeconomic imbalances (unemployment, balance of payment problems) should be incorporated in project analysis suffers from having excluded the programming approach to these questions. It certainly cannot be taken for granted—as the author does—that programming models cannot depict the real world situation and

that the shadow prices which they generate are "extremely crude" (p. 11). Many agricultural economists will be shocked at the rejection of the programming approach in helping to determine shadow prices in a variety of agricultural project settings. It could be argued that shadow prices generated by programming models are often as realistic and operationally useful as those generated by alternative partial equilibrium methods and, in any case, can provide a useful check on the latter.

The heart of the volume is contained in part 2, which is devoted to income distribution aspects. On the whole, the discussion is thorough, clear, and objectively presented. Helmers makes a strong and convincing case for the incorporation of the distributional effects of projects reflecting societal values. He starts by rightly rejecting the so-called compensation tests. If in reality compensation does not take place, it is totally irrelevant to use a test according to which the poor could, in principle, have been compensated. After undertaking an interesting critical review of the theoretical and empirical literature on the marginal utility of income schedule, the author concludes that even if it were possible to obtain accurate estimates of this schedule at different income levels, it still would not be appropriate to use these as weights to make interpersonal comparisons. The correct weights should be derived from societal values. This leads the author to postulate such weights for a typical developing country on the defensible assumption that society only cares about the very poor and the very rich and is relatively indifferent regarding the income distribution which prevails in between.

Even though projects should be subjected to the above type of social rate-of-return analysis, the author introduces what amounts to a lexicographic decision rule regarding project selection. First, only those projects whose economic rates of return are higher than the opportunity cost of capital should be accepted. It is only if this efficiency criterion is met that the second (equity) criterion—the social rate of return analysis—comes into operation. This guarantees that all projects have, at least, an acceptable economic rate of return. The above decision rule is, of course, normative and reflects a particular type of social welfare function which ignores equity considerations altogether, as long as a minimal efficiency threshold is not met. The selection rules adopted by the author might be interpreted as a compromise between the old traditional (efficiency-oriented) approach to project analysis and the evolving more equity-oriented approach.

The incorporation of distributional objectives in project analysis requires the latter to move away from a strictly microeconomic framework towards the no-man's land between micro- and macroeconomics. Perhaps, fearing to be soiled by such a move, Helmers adopts a negative position regarding a macroeconomic approach to development planning. To quote him: ' A poverty-focused strategy is necessarily a micro-economic strategy and must rely on project analysis to help determine which projects and which programs will indeed raise the incomes of the poor and which must be rejected" (p. 262). It would be more accurate to say that a combination of a conducive macroeconomic policy framework and microeconomic project analysis is required. In fact, Helmers seems to recognize this in his short section on national planning and project planning (pp. 13–15). The position of the author may be somewhat inconsistent on this issue.

In conclusion, this is a very good treatment of the theoretical underpinning of project analysis. This volume deserves to take its place among a small set of reference books in this area. It deserves to be read by practitioners and students of project analysis alike.

Hopkins, Raymond F., and Donald J. Puchala. ***Global Food Interdependence: Challenge to American Foreign Policy.*** **New York: Columbia University Press, 1980, xvi + 214 pp., $20.00.**

In the late 1970s, with the return of favorable weather and the consequent large harvests around the globe, the priority of food aid and food security issues on the agricultural policy agenda declined. This book is intended to refocus attention on these issues. The authors examine the U.S. policy response to world food issues in the 1970s and propose policies which would improve the ability of the United States to respond to future food needs.

Hopkins and Puchala's central thesis is that the global food system has not been performing satisfactorily and they recommend several policies to improve its performance. First, public policies are proposed to regulate vagaries of agricultural supply, rectify policy distortions, and restrict abuses of the marketplace. These policies include internationally managed grain reserves, bilateral trade agreements, and international commodity agreements. Second, they conclude that food aid is beneficial to recipient countries, and it is in the interest of the United States to continue food aid programs, probably indefinitely. Because of this, the United States should clarify food aid priorities and emphasize the developmental aspects of food aid. Third, the authors argue in favor of improved coordination between U.S. government agencies responsible for food aid. Specific recommendations include an increased role for middle level specialists on interagency committees, greater appreciation of food aid issues at senior levels, and better integration of the private sector into research and policy

deliberations. Fourth, they recommend a more active role for the United States in international food organizations. Finally, the authors argue for a more systematic consideration of long-range future scenarios in policy recommendations rather than relying only on short-term analysis.

The authors are explicit in stating the arguments underlying their policy recommendations. They are political scientists and take a broad view of the global food system, incorporating the economic, political, and social institutions that shape food policies. For example, they emphasize the political, legal, and institutional aspects of land in addition to economic factors. This broad perspective is one of the major contributions the book offers to agricultural economists. However, this general perspective may be troublesome for some economists. Although most of their economic arguments appear reasonable, many are based on concensus opinions of economists with little supporting empirical economic analysis.

Hopkins and Puchala's analysis leads to conclusions which will challenge some economists' views of global food issues. They criticize economic theorists for being more concerned with substituting abstract economic logic for empirical analysis and concrete policy recommendations. They write (p. 71), "A world of exploding populations, predictable food deficits, erratically fluctuating prices, and growing dependence upon an imperfect market is hardly served by philosophic debate [on grain reserves] in lieu of action." They also conclude for institutional and political reasons that food aid is a more realistic policy than income transfers. Some economists argue in favor of a cash transfer on the basis of economic efficiency. The authors contend that if serious efforts were made to substitute income transfers for food aid, diverse political interest groups would mobilize against the policy. Further, even if such counter-efforts failed, there is little reason based on the politics of foreign aid to expect that suspended food aid flows would be compensated by increased cash flows. Hopkins and Puchala's conclusions offer economists an opportunity to reexamine their policy recommendations on food issues.

The major contribution of the book is the balanced discussion of global food issues. They are concerned about the future, and while approaching global food issues with a sense of urgency, are optimistic. The policy recommendations reflect a belief that the existing system can be responsive to food needs, albeit with modifications. They do not condemn the current world food-trading system, but propose positive changes of limited scope, such as international grain reserves, and improved inter- and intra-government coordination. As might be expected, their policy recommendations probably will not satisfy the "hunger lobby," nor will they be acceptable to those who view the issue of global food security with skepticism. But the balanced concern of the authors is effective in refocusing attention on global food issues, and their policy recommendations are worthy of serious consideration by agricultural economists.

Philip L. Paarlberg
USDA ESS

Jackson, David H. ***The Microeconomics of the Timber Industry.*** **Boulder, Colo.: Westview Press, 1980, xiii + 136 pp., $18.50.**

The purpose of this book is "to provide a better linkage between microeconomic theory and forestry" (p. xii). To achieve his purpose, the author states two objectives: (*a*) theoretical development of the firm's timber supply function with time dependent production, and (*b*) aggregation of individual firm supply functions into a market supply function. These models are subsequently used to analyze the effect of various types of taxes on timber production and market supply. The central focus of the book is on the actions of private timber producers with little theoretical development of public timber supply or demand.

To develop the firm's supply function with time-dependent production, a wealth maximization model is constructed with output a function of establishment (reforestation) inputs and time. Time-dependent production necessitates the discounting of this wealth equation. Timber production is assumed the land's highest and best use; thus, the discounting procedure for an infinite series of timber rotations (production cycles) is used. Utilizing this equation, comparative statics are used to expand and modify Gaffney's 1957 financial maturity study. The major contribution of this analysis is that both time and input levels are allowed to vary rather than just harvest age as in Gaffney's study. This modification results in a lengthened rotation age instead of a shortened one, as predicted by Gaffney, given an increase in the interest rate.

In deriving the firm's supply function, optimal production decisions at two different output prices are compared. It is shown, assuming a fixed land base, that timber supply is a positive function of output price. The response to an increase in interest is negative. Additional production models of increasing complexity, including heterogenous product quality and n-decision alternatives, are presented, but are not used to derive more complex supply functions.

The industry's supply function is derived from the simple production function of one input and time. Since the firm's supply function is in terms of output per acre per unit of time, it must be multiplied by the acres in each firm and then added across all firms to derive the timber supply function for private industry. In this model, the land base is not fixed and changes in timberland acreage are viewed as the entry or exit of firms from the market.

Therefore, an elastic timberland market would result in a more elastic timber supply

To develop the timber market, public timber supply is assumed inelastic at a governmentally controlled output per year. A simple timber demand function is specified and market equilibriums under different conditions are analyzed.

In the fourth chapter (of five), there is an abrupt change in the subject matter from theoretical development to policy analysis. The previously developed models are utilized to determine tax impact and incidence on intrafirm resource allocation and market supply and price. Sales or excise taxes, capital gains taxes, and accrued income taxes are nonneutral and cause shifts in timber supply. Three kinds of land taxes and ordinary income taxes are shown to be neutral.

A shortcoming of the book is the lack of an in-depth discussion of the dynamics of the entry or exit of land from timber production. This deficiency arises from the assumption that timber production is the highest and best use of the land. Since the number of acres devoted to timber production could significantly influence supply responses, some type of land market is needed to determine the net impact of price and interest changes on supply. Another area of weakness is the derivation of the firm's supply function. The function is derived from a comparison of two static points rather than from the profit or cost function. While this is probably due to the inclusion of time dependent production, the author fails to explain this deviation from the more classic microeconomic development of the supply function. Numerous typographical errors make certain statements and equations difficult to understand.

The book's contribution is its demonstration of microeconomic theory in a forestry context. As such, it may be useful as a supplement to graduate courses in forest economics. Economists studying timber production or forest taxation also may find the book interesting.

Peterson, Trudy Huskamp. *Agricultural Exports, Farm Income and the Eisenhower Administration.* Lincoln and London: University of Nebraska Press, 1980, xii + 222 pp., $15.95.

When Dwight Eisenhower won the presidential election of 1952, the Republicans came steaming into office determined to uproot New Deal "socialistic" programs. One sector that they felt was ready for deep plowing was the farm income support apparatus. This included acreage allotments, price supports, and commodity diversions at home and abroad.

The direct payments of wartime had been discontinued, and Agriculture Secretary Charles F. Brennan's plan for such payments on perishable commodities was not enacted. Acreage limitations remained as the main instrument for reducing surpluses and holding up prices. Republican agricultural leaders proposed to get rid of this and handle the surplus problem by boosting export sales of grains, cotton, and other major products.

This book, by a historian with the National Archives and Records Service, describes the background and political maneuvering which brought forth the Food for Peace legislation of 1954 (Public Law 480) and the operation of the law in the Eisenhower years.

Food for Peace, that is, aid for poor countries, was a significant objective behind the new law, but commercial export development was even more important in the minds of the Farm Bureau leaders, who strongly advocated the program, and Ezra Taft Benson, the new Secretary of Agriculture. Sales of farm products abroad at submarket prices were to pave the way for expanded commercial trade. Donations also would promote American foodstuffs. This would overcome the surplus plague and avoid the ideologically repellent crop controls. (Government intervention in foreign trade apparently was less dreadful to the G.O.P. ideologues.)

Export subsidies were not new, of course; they had been used in various ways—Export-Import Bank loans, Marshall Plan grants and loans, Section 32 funds from customs' revenues used for export subsidies, and Commodity Credit Corporation relief sales and donations, as well as barter trades with agricultural commodities. P.L. 480 was a plan to enlarge and systematize the whole business.

Secretary of State Dulles saw the program as a tool for pursuing political aims in strategic areas. The new law authorized sales to "friendly" countries—not to the USSR or a country "dominated or controlled by the foreign government or foreign organization controlling the world Communist movement." How times have changed! In 1972, Soviet grain purchases were welcomed with subsidies. A partial grain embargo on sales to the Soviet Union in 1980 was regarded as intolerable by the same pressure groups which applauded the P.L. 480 embargo.

P.L. 480, like the export disposal programs which preceded it, proved to be an inadequate substitute for crop acreage limitation as a means of supporting farm income. Surpluses still accumulated in the 1950s, and in the 1960s crop acreage controls returned.

Peterson's book is an elaborately documented

study, as would be expected from an archivist. The author relied heavily on papers of USDA luminaries, including those of Don Paarlberg, a Fellow of this Association who was an economic adviser to Benson and later Food for Peace administrator. Paarlberg was one who cautioned against excessive dumping of commodities, fearing that this would undermine commercial markets, including those of U.S. allies—which it did to some extent. But these warnings were overridden by the impulse to shuck the government control system at home.

One inheritance of the program is the dependence of many less developed countries on the U.S. granary for their reserves, which has inhibited rather than helped agricultural development in those countries. Another was the misuse of Food for Peace to pursue military and political objectives instead of economic aid. These outcomes were foreshadowed in some degree during the debates prior to enactment of P.L. 480—but ignored.

The Peterson book is valuable for reference, despite a lack of sophistication in interpretation of the underlying economic issues. It is excellent as a reporting job on the politics of agricultural trade during the 1950s.

Lauren Soth
West Des Moines, Iowa

Schmitt, Bernard A. *Protein, Calories and Development.* Boulder, Colo.: Westview Press, 1979, xxi + 224 pp., price unknown.

In the foreword to this book, Ray Canterbury describes its scope as staggering. Indeed, the book more fruitfully could have become three journal papers. The first part of the book, covering the first three chapters, is a useful overview of recommended daily allowances for proteins and calories and the importance of diet quality as an indicator of food adequacy. The second part, chapters four and five, is about projections of domestic food production for developing countries using cross-sectional data. The balance of the book, chapters six and seven, is a yet-to-be-finished paper on food policies. Forecasts are developed for a number of food commodities that represent the principal sources of energy and protein in human diets (wheat, rice, coarse grains, pulses, sugar, starches, and livestock products). The work is innovative because the productive capacity of agricultural labor is augmented through three measures of food availability (a nutritional index, per capita calories, and per capita proteins). The approach is described as the "cyclonutritional" phenomenon whereby nutrition (food intake) is said to affect human capital, which in turn affects agricultural output through enhanced labor productivity.

Data for 1970 from developing countries that are significant producers of each commodity are used in the estimation of unrestricted Cobb-Douglas production functions. Labor, land, and fertilizer are used as conventional factors of production to explain physical output of each commodity. Technology differences among countries are said to be held constant in the regression analyses by including a technological index. The technological index is a complex composite of several ordinal and nominal scales of concepts such as mass communication, political commitment to economic development, character of the agricultural organization, and modernization of techniques in agriculture as well as indices developed by other authors. The rationale and scalar properties of the technological index is not complete and lacks specificity on what the index measures.

The data-processing effort is impressive. About seven of the twenty (or so) regressions which were run for each commodity are presented. No logic is given for the particular choice of variables in the regression results that are presented. Furthermore, there is no consistency of presentation, so that the effect of a given variable in one commodity may not appear in the same specification for another. Thus, there is no clarity regarding the hypotheses being tested.

The estimates of the effect of conventional factors seem robust across equations within commodities. Estimates are presented as output elasticities without reference to what is being held constant. The estimated effects of land are presented as substantially larger than the estimates of other authors, yet no meaningful effort to explain the differences is presented. The results are said to point out the importance of land in developing agriculture as opposed to the capital intensive agriculture of developed countries. Furthermore, the claim is made that the technology index eliminates any confounding of the land effect. The technology index was not significant for wheat production, and this was explained away by appeal to a colinearity with fertilizer. Yet data for Argentina, Mexico, and India are excluded from the wheat regressions, as are irrigation and high yielding varieties.

The stated novelty in the analysis is the inclusion of nutritional variables. Two equations are presented which show proteins as significant, another two show the quality-adjusted nutritional index as significant, and yet another two equations show each of these to have a significant interaction with labor. In these latter two, no main effects are tested, so it is not clear that the interaction effect is significant, per se. Much of the main policy recommendation hinges on this result.

Selected output elasticities are then combined with projections of factor use to 1985 to project country-by-country output for each commodity. The projections and forecasts all assume constant relative prices and no reallocation of factors among commodities. When compared against United Nations Food and Agricultural Organization demand projections, all commodities, except sugar and

pulses, show deficit balances. These imply a shortfall of 120 to 174 calories per capita per day in the developing world. This is a cereal equivalent of 60 million metric tons per annum.

In the conclusions, trade and aid are said to be insufficient to fill the gap. The "Green Revolution" is said to be included already in the data (recall the exclusion of Mexico and India from the wheat analysis) and to contribute little because the new high-yielding varieties are fertilizer-intensive. Land and fertilizer use would have to be increased by half again the projected growth to fill the forecasted nutrient gaps. A redistribution of nutrients to agricultural labor could yield multipliers of 1.1 to 1.2 on food output. Nothing is said about how this targeted food transfer is to be achieved. The conclusions and policy recommendations form an interesting set of hypotheses on which to begin work on the third paper.

David L. Franklin
Research Triangle Institute

Stevens, Christopher. *Food Aid and the Developing World*. New York: St. Martin's Press for the Overseas Development Institute, 1979, 224 pp., $22.40.

This book does not do precisely what its title implies. It focuses on four African recipients (Botswana, Lesotho, Tunisia, and Upper Volta), and the first six chapters present a miscellany of facts and figures about the food aid practices of each of the donors active in those four countries and the experience of each of the four countries in administering various types of food aid projects and programs.

Yet, the focus on Africa is an important contribution of the book, and it leads in an indirect way to the more general insights the author clearly wishes to convey. Much of the earlier empirical literature considers the experience of the larger food aid recipients in Asia and Latin America. Focusing on Africa provides a perspective on smaller recipients and on the targeted project approach which has been missing from previous work. To the author's regret, empirical data for doing rigorous impact analysis are simply not to be had in these or other small African countries. This lack does not prevent him from giving good evidence for each of the points he wishes to make. The chapters on the recipients and on the uses of food aid (3, 4, 5, and 6) could have been improved by a greater effort to provide comparable secondary data for all of the countries and to give a clearer statistical picture of the relation of food aid flows to domestic production and total imports in quantitative terms. However, the net result of Stevens' more spotty use of numbers is still to give a fairly clear picture of how food aid operates within the economic and political framework of each of the four countries under study.

A second valuable contribution is Stevens' taxonomy of the uses of food aid. By distinguishing three generic types of food aid and classifying various types of targeted projects and bulk supply programs accordingly, he sharpens our understanding of the relation between different food aid objectives and the approach selected for implementation. His three categories are food for cash, food for nutrition, and food for work. The primary aim of food for cash, in his view, is "to realize the money value of the food aid," which can be achieved either through open market sales or through institutional feeding programs, as in secondary schools and hospitals. The primary aim of food for nutrition is to improve the nutritional status of people who are particularly vulnerable or deserving, which is usually attempted through mother/child feeding programs or through primary school lunches. The primary aim of food for work is to subsidize productive employment for the very poor by providing a ration of food in lieu of cash wages, which can be accomplished either through public works projects or through resettlement and farmer incentive schemes.

In chapters 7, 8, and 9 Stevens presents his conclusions and findings with respect to the impact of food aid on nutrition, consumer prices, and agricultural production. In these chapters he reviews the evidence from individual projects and programs in each of the four study countries. Because his four countries are each quite different and the coverage of different types of food aid activities is broad, these chapters are sprinkled throughout with interesting microlevel observations. Stevens gives plenty of specific instances in which food aid has had a negative impact. Nevertheless, his examples of positive, though sometimes unintended, results are sufficiently numerous to justify his more general point that there is nothing inherent about food aid to support some critics' claims that its effects will always be bad.

Christopher Stevens stands firmly with those who believe food aid can be a useful development assistance tool. In his concluding chapter (10), he gives some cogent reasons for this view. For one thing, he points out that "for political reasons it is difficult to focus openly on two of the most attractive features of food aid: first, that it often represents free foreign exchange, and second that it is a subtle means of providing income-in-kind to poorer people" (p. 204). Support for food aid comes from exporters, who want the food to be additional to commercial imports, and hunger lobbies, who want the food to feed the starving millions. Since the real accomplishments of food aid are not the ones its strongest supporters advocate, it is clear why food aid is in trouble in some quarters, despite its potential importance for development in many third world countries.

For another thing, in the effort to link food aid more effectively to rural development activities,

both supporters and critics judge the effectiveness of the linkage according to whether or not the activities supported are the most promising for rural development. To Stevens, this is a fundamentally misguided approach. Food aid, he says, "should be used in activities that can use it effectively and are not destabilized by it" (p. 207). Those who claim that some methods of disbursing food aid are inherently superior to others simply because they link directly to fashionable projects or policies would actually constrain food aid from being used in the variety of ways necessary to achieve its maximum potential effectiveness.

For those who read it and absorb its message, Stevens' book should help clarify what food aid can and cannot do and give practical guidance to those actively attempting to improve its developmental effectiveness.

Ahmed Humeida Ahmed, B.S. 1970, M.S. 1976, Khartoum University; Ph.D. Ohio State University, "Recent Performance of Rural Financial Markets in the Sudan, 1965–1979."
Robert Gene Aukes, B.S. 1974, M.S. 1977, Montana State University; Ph.D. University of Illinois, "Effects of Variable Amortization Plans on Borrower and Lender Risk: A Simulation Study of Low Equity Illinois Cash Grain Farms."
Girma Begashaw, B.S. Haile Selassie University, 1973; M.S. Michigan State University, 1976; Ph.D. Ohio State University, "Evaluation of a Supervised Credit Project in Jamaica."
Ivan Sergio Freire de Sousa, B/Licentiate, Pontifica Universidad de Sao Paulo, 1969; M.S. University of Sao Paulo, 1974; Ph.D. Ohio State University, "Accumulation of Capital and Agricultural Research Technology: A Brazilian Case Study."
Glenn D. Pederson, B.S. University of Minnesota, 1973; Ph.D. Michigan State University, "A Conceptualization and Analysis of the Distributional Impacts of Alternative Agricultural Credit Policies."
MD. Luthfor Rahman, B.A. Dacca University, 1962; M.S. 1966, Ph.D. Texas A&M University, "Variable Amortization and Financial Control under Uncertainty."
Luis Roberto Sanint, B.S. University of Los Andes, Bogota, Colombia, 1974; M.S. 1976, Ph.D. Texas A&M University, "Lenders' Credit Response to Farm Income Risks in Texas: A Multiperiod Risk-Programming Analysis of Credit Reserves."
Mohamed H. Takroni, B.S. University of Idaho; M.S. New Mexico State University; Ph.D. Oklahoma State University, "Evaluating Loan Repayment in the Saudi Arabian Agricultural Sector by Means of Farm Credit Interdependent System."

The names of Ph.D. recipients are provided by departments of agricultural economics and by departments of economics with majors in agricultural economics. The list is for degrees granted in the calendar year 1980, unless otherwise stated.

Fred Eugene Williams, B.S., M.E., Ph.D. North Carolina State University, "Capitalized Allotment Values as Indices of the Uncertainty with Which Farmers Perceive Future Tobacco Programs."

Agricultural Labor; Rural Manpower

Marietta S. Adriano, Ph.D. Purdue University, "The Impact of an Irrigation Project on Labor Intensity and the Distribution of Income: The Case of the Sibalom Irrigation Project in Iloilo, Philippines."
David Thomas Barker, B.S. New York State University, Brockport; M.E., Ph.D. North Carolina State University, "An Analysis of Short-run Changes in Retirement Behavior Using a Life-Cycle Model."
Juan Diez-Canedo-Ruiz, Lic., Instituto Tecnologico de Mexico, 1973; Ph.D. Massachusetts Institute of Technology, "A New View of Mexican Migration to the United States."
Thomas M. Dickey, B.S. Oklahoma State University, 1968; M.S. 1974, M.A. 1974, Ph.D. Michigan State University, "The Puerto Rico Wage Rate Subsidy for Agricultural Labor."
Teresa Jayme Ho, B.S. 1971, M.A. 1974, University of the Philippines; Ph.D. Stanford University, "The Labor Market for Married Women in the Rural Philippines."
Wuttithep Indhapanya, B.A. Thammasat University; M.E., Ph.D. North Carolina State University, "Some Aspects of Migration in the Philippines: An Empirical Model of Family Migration."
Winthrop Hubbard Segur, B.S. Trinity College, 1958; M.A. Bowdoin College, 1965; M.S. 1975, Ph.D. University of California, Davis, "Representative Elections for Farm Workers: Voting Power under Alternative Rules of Eligibility."

Agricultural Products: Demand, Supply, Prices

Shashanka Bhide, B.S. University of Agricultural Sciences, 1973; M.S. Indian Agricultural Research Institute, 1975; Ph.D. Iowa State University, "A Separable Programming Model Incorporating Linear Demand Functions for Grains and Vegetable Oils: An Analysis of United States Agriculture in 1985."
Steven C. Blank, B.A. California State College, Stanislaus; M.B.A. University of Massachusetts; Ph.D. University of Hawaii, "A Study of Futures and Cash Prices of Beef Cattle—Relating Theory to Fact for a Nonstorable Commodity."
Harlan N. Burnstein, M.S. 1975, Ph.D. Pennsylvania State University, "An Econometric Analysis of the Aggregate Acreage Response to Fluctuation in Farm Prices and Revenues."
Gurprit Chhatwal, B.S. Punjab Agricultural University, India; M.S., Ph.D. Kansas State University, "Distinctive Effect of P.L. 480 Wheat Imports for India."
Ashok Kumar Chowdhury, B.S. Govind Ballabh Pant University of Agriculture and Technology, 1973; M.S. Indian Agricultural Research Institute, 1975; Ph.D. Iowa State University, "Competitive Partial Equilibrium Analysis of U.S. Agriculture under Alternative Energy and Export Situations—Application of Separable and Chance Constrained Programming."
Roger Alan Dahlgran, B.S. Iowa State University; M.E., Ph.D. North Carolina State University, "Acreage Response to Government Pest Control Programs: The Case of Boll Weevil Eradication."
Christopher Douglas Easter, B.S. 1970, B.S. 1971, University of Newcastle Upon Tyne, England; M.S. 1978, Ph.D. University of California, Davis, "Supply Response with Stochastic Technology and Prices in Australia's Rural Export Industries."
J. R. Groenewegen, B.S. 1975, M.S. 1976, University of Guelph; Ph.D. University of Minnesota, "Corn and Soybean Acreage and Yield Response with Emphasis on Multiple Product Production, Uncertainty, and Commodity Programs."
John David Hanson, B.S. 1975, Ph.D. Iowa State University, "An Information Theory Analysis of Grades and Grading with an Application to Beef Cattle."
Apisith Issariyanukula, B.S. Kasetsart University, 1971; M.S. National Taiwan University, 1974; Ph.D. Washington State University, "An Econometric Analysis of the Supply and Demand for Soybeans in Thailand."
Thomas A. Loudat, B.A. University of California, Santa Barbara; M.S. California Polytechnic State University; Ph.D. University of Hawaii, "An Economic Analysis of the Competitive Position of the Hawaii Banana Industry in the Honolulu Market."
Subobh Chaud Mathur, B.A. 1970, M.A. 1972, Delhi University; Ph.D. Massachusetts Institute of Technology, "The Economics of the Commodities Fund: An Aspect of the New International Economic Order."
Stephen Gichovi Mbogoh, B.S. 1974, M.S. 1976, University of Nairobi; Ph.D. University of Alberta, "An Economic Analysis of Kenya's Sugar Industry with Special Reference to the Self-Sufficiency Production Policy."
Judas Tadeu Grassi Mendes, Engineer, Federal University of Paraná, 1971; Graduate, Federal University of Rio Grande do Sul, 1976; Ph.D. Ohio State University, "Soybean Marketing Strategies: A Portfolio Analysis."
Sahathavan Meyanathan, B.Ec 1972, M.Ec. 1974, University of Malaya; Ph.D. Stanford University, "Evaluation of the Proposed Rubber Agreement under the Integrated Programme."
Thongchai Petcharatana, B.E. Thammasat University, 1963; M.E. North Carolina State University, 1969; Ph.D. Washington State University, "Supply, Demand and Price Analysis for Rice in Thailand."
Jeffrey W. Pyne, B.S. University of Wisconsin;

M.S. University of Illinois; Ph.D. University of Hawaii, "The United States Cattle Cycle: A Quantitative Analysis."

Tsunehisa Tamaki, Agronomist 1967, M.S. 1976, Universidad de Sao Paulo; Ph.D. Ohio State University, "The Spatial Price Equilibrium Activity Model of the World Coffee Economy with Emphasis on Soluble Coffee."

M. H. Tracy, B.S. Cornell University; M.S., Ph.D. University of Maryland, "Producer-Financed Commodity Advertising: An Examination of the Egg Research and Promotion Program."

Cooperatives and Cooperation

Mark D. Newman, B.A. Pennsylvania State University, 1972; M.S. 1978, Ph.D. Michigan State University, "An Evaluation of the Economic Potential for Coordination of Export Marketing by U S. Farmer Cooperatives."

Buggaran Saragih, B.S. Bogor Agricultural University; M.E., Ph.D. North Carolina State University, "The Case of Oil Palm Plantations in Northern Sumatra, Indonesia."

Peter Vitaliano, B.A. Indiana University, 1966; M A. Pennsylvania State University, 1972; Ph.D. University of Wisconsin, "A Comparative Analysis of the Cost of Long-Term Debt Financing for Regional Marketing Cooperatives and Investor-Owned Firms in the U.S. Agricultural and Food Industries."

Economic Development, Growth and Planning

Valentine Jervis Akenda-Ondoga, B.S. Makerere University; M.S., Ph.D. Cornell University, "An Economic Study of Production Organization and Labor Use among Smallholders of Nile Province, Uganda."

Gordon Roy Banta, B.S. 1963, M.S. 1967, Ph.D. University of Alberta, "Asian Cropping Systems Research: Micro-Economic Evaluation Procedures."

Harry Emil Brautigam, Lic. Universidad Autonoma de Guadalajara, 1971; Dipl. Victoria University of Manchester, 1973; M.A. University of Leeds, 1974; Ph.D. University of Illinois, "Analysis of Objectives of the Development of the Agricultural Frontier of Nicaragua."

Konstantinos Dimitrios Christou, Graduate, University of Salonika, 1970; M.S. 1976, Ph.D. University of California, Berkeley, 1979, "Greek Agricultural Development and Integration with European Communities."

Gary Peter Ender, B.S. Massachusetts Institute of Technology; M.S., Ph.D. Cornell University, "The Development of Road Transportation in Nepal and Its Relationship to Agricultural Development."

Marco Antonio Ferroni, Baccalaureat Kantonsschule Oblsalben, Demi-Lic. University of Geneva, Switzerland; M.S., Ph.D. Cornell University, "The Urban Bias of Peruvian Food Policy: Consequences and Alternatives."

M. T. Futa, B.S. University of Zaire; M.S. University of Florida; Ph.D. Oklahoma State University, "An Integrated Evaluation of Agricultural Research in Tropical Africa: Case of Nigerian Food Crops Research System."

William Grisley, B.S. University of Wisconsin, 1969; M.S., Ph.D. University of Illinois, "Effect of Risk and Risk Aversion on Farm Decision-Making: Farmers in Northern Thailand."

Larry W. Harrington, B.A. 1969, M.S. 1978, Ph.D. Michigan State University, "Farmer Assessment of Maize Recommendations in Northern Veracruz State, Mexico."

Saleh H. Humaidan, B.S. University of Arizona; M.S. University of Florida; Ph.D. Oklahoma State University, "Policies and Management Guidelines for Optimum Resource Utilization at Al-Hasa Irrigation and Drainage Project, Saudi Arabia."

Gary S. Kemph, B.S. Texas A&M University, 1969; Ph.D. Michigan State University, "The Impact of Local Government Policies on Land Values and Appreciation."

Richard Allan Mines, A.B. 1966, A.B. 1970, Ph.D. University of California, Berkeley, " 'Las Animas, California': A Case Study of International Village Network Migration."

Joseph Viyof Ntangsi, Graduate, Catholic University of the Sacred Heart, Milan, 1970; M.S. 1975, Ph.D. University of California, Berkeley, "The Political Economy of Rural Development in Cameroon."

Douglas Henry Pachico, B.A. San Francisco State University; M.S., Ph.D. Cornell University, "Small Farmer Decision Making: An Economic Analysis of Three Farming Systems in the Hills of Nepal."

Uben Parhusip, B.A. Bogor Institute of Agriculture, 1966; M.S. 1976, Ph.D. Michigan State University, "Strategies for Increasing Food Production and Income on Small Upland Farms in Lampung, Indonesia—A Linear Programming Analysis."

Zvi Ron, B.A. Tel Aviv University, 1971; M.S. Hebrew University of Jerusalem, 1976; Ph.D. Pennsylvania State University, "Agricultural Variation and Household Behavior: A Microeconomic Analysis of Human Fertility among Thai Rice Farm Families."

T. P. Sendjaja, B.S. Padjadjaran University; Ph.D. University of Tennessee, "Perspective Analysis of Small Community Capital Accumulation (PASCCA): A Model for Diagnosing Local Impacts of Agricultural Changes, with Applications to West Java Rice Villages."

Fernando Julio Viana de Brito Soares, Engineer, Technical University of Lisbon, 1968; Ph.D. University of California, Berkeley, "Programming Analysis Related to Agricultural Planning in Portugal."

Sumter Lee Travers, Jr., B.S. 1973, M.S. 1974, Ph.D. University of California, Berkeley, "Choice of Techniques and Agricultural Modernization in China."
Sweder Jan-Gijsbert Van Wijnbergen, Kand (Phys.), Kand (Econ.), Rijksuniversiteit Utrecht, 1972; Ph.D. Massachusetts Institute of Technology, "Credit Policy, Inflation, and Growth in Less Developed Countries."
Vivianne Ventura-Dias, Architect, Mackenzie University, Sao Paulo, Brazil, 1967; M.C.P. 1975, M.S. 1978, Ph.D. University of California, Berkeley, "Small and Large Enterprises in the Brazilian Textile Industry: The Modernization of a Traditional Industry."
Elsayed Ali Ahmed Zaki, B.S. 1967, M.S. 1970, University of Khartoum; M.A. 1977, Ph.D. Michigan State University, "An Ongoing Evaluation of the Planning, Implementation and Tenancy (Farm) Size of the Rahad Irrigation Project of the Sudan."

Energy

Richard George Anderson, B.A. University of Minnesota, 1972; Ph.D. Massachusetts Institute of Technology, "Energy Conservation and Factor Substitution in U.S. Manufacturing 1947–1971."
M. A. Litterman, B.S. 1974, Ph.D. University of Minnesota, "Energy Substitution in U.S. Manufacturing and Agriculture."
Juvir Luiz Mattuella, B.S. 1968, M.S. 1974, Porto Alegra; Ph.D. Ohio State University, "Economic Impact of Alcohol Production on Agriculture in Southern Brazil."
Larry Joe Moffitt, A.B. 1973, Ph.D. University of California, Berkeley, 1979, "A Disequilibrium Analysis of Agricultural, Commercial and Consumer Gasoline Demand."
Margo Beth Rich, B.S. Cornell University 1973; Ph.D. Stanford University, 1979, "Residential Energy Conservation and Price Response."
Jeffery R. Williams, B.S. Pennsylvania State University, 1975; M.S. 1977, Ph.D. Michigan State University, "An Economic Analysis of the Feasibility of the Retort Pouch for Packaging Fruit and Vegetable Commodities in an Environment of Rising Energy Prices."

Environmental Economics; Conservation

Theodore Richard Frickel, B.A. University of Colorado, 1966; M.A. Northeastern University, 1975; Ph.D. Utah State University, "Economic Impacts of Irrigation Technologies in the Sevier River Basin."
Carl Christian Mabbs-Zeno, B.A. University of Connecticut 1974; M.S. University of Georgia, 1977; Ph.D. Virginia Polytechnic Institute and State University, "Institutional Purpose and the Management of Virginia's Coastal Wetlands."
William Claude Kinney, B.S. Stanford University, 1970; M.S. 1976, Ph.D. University of California, Davis, "Land-Use Conflict in Wildland Watershed Management: A Multiple Objective Economic Analysis."
William Mills Park, B.A. Depauw University, 1974; M.S. Purdue University, 1976; Ph.D. Virginia Polytechnic Institute and State University, "The Role of Benefit Taxation and Cost Sharing in Nonpoint-Pollution Management."
Ricardo Rodriguez-Dorbecker, Lic. en. Economia, Esc. Nal. de Economia; M.S. Centro de Economia Agricola; Ph.D. North Carolina State University, "Acreage Response to Government Pest Control Programs: The Case of Boll Weevil Eradication."
Webb Morrow Smathers, Jr., B.A. University of North Carolina, Ashville, 1970; B.A. 1972, M.S. 1974, Ph.D. University of Kentucky, "A Mixed Integer Method for Analyzing the Impact of Surface Mining Regulations on Economies with Public and Private Goods."
David Zilberman, A.B. Tel Aviv University, Israel, 1972; Ph.D. University of California, Berkeley, "A Putty Clay Approach to Environmental Quality Control."

Food and Consumer Economics

R. Hinson, B.S., M.S., Ph.D. University of Tennessee, "Household Budget Allocation: The Interrelationship between Fixed Expenses and the Purchase of Food."
Anne Margaret Thomson, B.A. Cambridge University, England, 1972; Ph.D. Stanford University, "Nutrition, Food Demand and Policy."

Industrial Organization; Market Structure

Ella Kay Carl, B.A., M.A., M.A.M.R.D., Ph.D. University of Florida, "Selection of Alternate Vertical Exchange Mechanisms and Its Effects on Market Price."
Wilson C. Chase-Lansdale, A.B. Harvard University, 1974; Ph.D. Michigan State University, "The Political Economy of Farmer Bargaining: Cooperative and Proprietary Processor Responses to Farmer Bargaining."
Peter W. Philips, B.A. Pomona College, 1970; M.A. 1977, Ph.D. Stanford University, "Towards a Historical Theory of Wage Structures: The Evolution of Wages in the California Canneries—1870 to the Present."

Marketing and Location

Bruce L. Anderson, B.S. Cornell University, 1968; M.S. Purdue University, 1972; Ph.D. University of

California, Berkeley, "The Economic Potential of Cooperative Integration in the California Cotton Industry."
Kim B. Anderson, B.S., M.S., Ph.D. Oklahoma State University, "Coordinative Efficiency of Grades and Standards for Feeder Cattle."
Colin Andre Carter, A.B. 1975, M.S. 1976, University of Alberta; M.A. 1978, Ph.D. University of California, Berkeley, "Grain and Oilseeds Futures Markets: Portfolio and Efficiency Analyses."
Lowell Bee Catlett, B.S. West Texas State University, 1973; M.S. New Mexico State University, 1975; Ph.D. Iowa State University, "Commodity Options as an Alternative to Hedging Live Cattle."
Kareko M. Gatere, B.S. 1972, M.S. 1974, Makerere University; Ph.D. University of Alberta, "Market Efficiency in Kenya: A Study of the Marketing System for Fruits and Vegetables."
Orlen Curtis Grunewald, B.A. University of Wisconsin, Green Bay, 1973; M.S. 1975, Ph.D., University of Kentucky, "A Risk Programming Analysis of the Role of Hedging in the Kentucky Feeder Cattle Industry."
Linwood Allen Hoffman, B.S. 1970, M.S. 1972, Pennsylvania State University; Ph.D. University of Illinois, "The Economic Effects of Demand-Sensitive Railroad Rates upon the Storage and Transportation System for U.S. Feed Grains."
Christopher Allan Hurt, B.S. University of Illinois, 1971; M.S. Cornell University, 1973; Ph.D. University of Illinois, "Impact of Price Risk on Aggregate Farrowing Response."
Stephen Gichovi Mbogoh, B.S. 1974, M.S. 1976, University of Nairobi; Ph.D. University of Alberta, "An Economic Analysis of Kenya's Sugar Industry with Special Reference to the Self-Sufficiency Production Policy."
A. Lee Meyer, Ph.D. Purdue University, "Obstacles to Carcass Grade and Weight Marketing of Livestock."
Philip Woodrow Pepper, B.S. 1970, M.S. 1974, Mississippi State University; Ph.D. University of Illinois, "A U.S. Corn Stocks and Consumption Demand Model."
Charles Daniel Safley, B.S., M.S. University of Tennessee; Ph.D. Oklahoma State University, "World Feed Grain Projected Production-Consumption Balances, U.S. Exports, and Price Variability."
Stephen P. Skinner, B.A. Central Connecticut State College, 1972; M.A. University of Rhode Island, 1975; Ph.D. University of Connecticut, "Production Response and Structural Change in the Connecticut, Massachusetts and New Hampshire Egg Industries Resulting from Adjustments in the Level of Freight Rates."
Peter Kristian Thor, B.S. 1976, M.S. 1977, Ph.D. University of California, Davis, "An Economic Analysis of the Marketing Orders for the California-Arizona Orange Industry."
Clyde A. Vollmers, B.S. 1968, M.S. 1970, North Dakota State University; Ph.D. Michigan State University, "An Economic Analysis of a Grain Logistic System: A Michigan Case Study."
Alan John Webb, B.A. American University; M.A. University of Arkansas; Ph.D. Oklahoma State University, "Impact of Projected World Wheat Production-Consumption Balances on U.S. Exports and Prices."
William W. Wilson, B.A. North Dakota State University, 1975; Ph.D. University of Manitoba, "Financing the Operation and Rehabilitation of Rail Branch Lines."

Natural Resource Economics

Donald Ray Andrews, B.S. Southern University, 1971; M.S. University of Florida, 1974; Ph.D. Texas A&M University, "Economic and Fiscal Impacts of Lignite Development for the Brazos Valley Economy of Texas."
Nancy Theresa Gallini, A.B. 1973, M.A. 1974, University of Missouri; Ph.D. University of California, Berkeley, "Research and Development of an Exhaustible Resource Substitute: The Case Study of Synthetic Oil."
Ronald C. Griffin, B.A. 1975, M.A. 1977, Colorado State College; Ph.D. University of Wisconsin, "Irrigated Agriculture and Nitrate Pollution of Rural Water Supplies: Economics for Policy in Central Wisconsin."
Thomas Parkin Hunter, B.S., B.A. University of the South; M.S., Ph.D. North Carolina State University, "The Geographic Variation of Southern Pine Timber Prices."
George M. Johnston, B.A. George Washington University, 1966; Ph.D. Michigan State University, "The Impact of Local Government Policies on Land Values and Appreciation."
David Henderson Laughlin, B.S. 1972, M.S. 1977, Mississippi State University; Ph.D. Texas A&M University, "The Agricultural Benefits of Salinity Control on the Red River of Texas and Oklahoma."
Sumol Padungchai, B.S. Chulalongkorn University, 1973; M.S. 1975, Ph.D. Utah State University, "An Economic Analysis of Water Quality Improvement Policies: The Optimal Combination of Salinity Control Techniques."
Karl Samples, B.S. Georgetown University, 1975; M.S. 1978, Ph.D. University of Wisconsin, "An Economic Analysis of Integrated Fisheries Management: The Case of the Lake Michigan Alewife/Salmonid Fisheries."
Robert Arnold Solove, B.A., M.A., Ph.D. University of Florida, "The Agricultural Impact of Water Quality Standards: A Mathematical Programming Approach."
John Raymond Stoll, B.S. University of Wisconsin, Green Bay, 1973; M.S. 1977, Ph.D. University of Kentucky, "The Valuation of Hunting Related Amenities: A Conceptual and Empirical Approach."

Production Economics and Management

Gordon Roy Banta, B.S. 1963, M.S. 1967, Ph.D. University of Alberta, "Asian Cropping Systems Research: Micro-Economic Evaluation Procedures."
Jose Baldeci Biserra, Diploma of Engineer Agronomo, Universidade Federal do Ceara, Fortaliza, 1969; M.S. Universidade de Sao Paulo, Piracicaba, 1971; Ph.D. Ohio State University, "Uncertainty and Decision Analysis on Large Sharecropped Farms in Northeast Brazil."
Angus Chidebelu, B.S. University of Nigeria; M.S. University of Guelph; Ph.D. University of Georgia, "An Analysis of Factors Affecting the Commercialization of Limited Income Farms in Georgia."
Eric Winthrop Crawford, B.A. Pomona College; M.P.A. Woodrow Wilson College; Ph.D. Cornell University, "A Programming-Simulation Study of Constraints Affecting the Long-Run Income-Earning Ability of Traditional Dryland Farming Systems in Northern Nigeria."
Richard Lewis Farnsworth, A.B. Brigham Young University, 1972; M.S. 1976, Ph.D. University of California, Berkeley, "A Decision Theoretic Analysis of Alternative Pest Control Strategies: A Case Study of Cotton Growers in California."
Sushma Sharma Ganguly, B.A. 1969, M.A. 1971, University of Delhi; M. Phil. Jawaharal Nehru University, 1976; Ph.D. Clemson University, "A Risk-Return Analysis of Irrigating Field Crops in South Carolina."
Richard M. Klemme, Ph.D. Purdue University, "An Economic Analysis of the On-Farm Grain Handling Decision Problem, Vol. I & II."
G. L. Knowles, B.S. 1973, Ph.D. University of Minnesota, "Estimating Utility of Gain Functions for Southwest Minnesota Farmers."
Ghanbar Kooti, B.A. Jondi Shapoor University, 1974; M.S. 1980, Ph.D. Michigan State University, "The Relationship between Land Values and Factor Costs."
Steven Edwin Kraft, B.A. American University; M.S., Ph.D. Cornell University, "Performance Classification of New York Soils: The Farmer's Perspective."
Banterng Masang, B.S. Thammasart University, 1968; M.S. 1975, Ph.D. Iowa State University, "An Application of Bayesian Decision Models in Evaluating Net Returns of Paddy Farm Storage by Farmers in the Central Plain of Thailand."
Thomas J. McGuckin, B.A. Pomona College, 1972; M.S. Colorado State College, 1976; Ph.D. University of Wisconsin, "An Economic Assessment of Alfalfa Dewatering Technology in Wisconsin."
Ndanusa Braimah Mijindadi, B.S. Ahmadu Bello University; M.A. University of Leeds; Ph.D. Cornell University, "Production Efficiency of Farms in Northern Nigeria."
Arun Kumar Misra, B.S. 1963, M.S. 1965, Orissa University of Agriculture and Technology; Ph.D. University of Missouri, "An Economic Evolution of Problems and Production Potentials of Small Farms in Orissa, India."
Abdoulaye Niang, Ph.D. Purdue University, "A Linear Programming Model of a Representative Sahelian Farm: The Cases of the Cotton Zone in Mali and the Peanut Zone in Senegal."
Dennis Terrence O'Brien, B.S. University of Sydney, 1970; M.S. University of Manitoba, 1974; Ph.D. Oregon State University, "Risk and the Selection of Alternative Weed Management Technologies in Philippine Upland Rice Production."
Abraham Ovedṭji Ogungbile, B.S. Western Illinois University, 1972; M.S. University of Missouri, 1974; Ph.D. Iowa State University, "An Evaluation of Improved Sole-Crop Production Technology on Small Farms in Northern Nigeria under Different Farm Power Sources: A Multi-period Linear Programming Approach."
Tillak Persaud, B.S. University of Illinois; M.S. University of Idaho; Ph.D. Oklahoma State University, "Decision Making Relating to Risk Management Strategies in a Farm Planning Model."
James Alfred Petty, B.S. Abilene Christian College, 1957; M.S. Texas Tech University, 1970; Ph.D. Texas A&M University, "Impact of Alternative Energy Prices, Tenure Arrangements and Irrigation Technologies on a Typical Texas High Plains Farm Firm."
Peter W. Philips, B.A. Pomona College, 1970; M.A. 1977, Ph.D. Stanford University, "Towards a Historical Theory of Wage Structures: The Evolution of Wages in the California Canneries—1870 to the Present."
Joel Plath, B.A. University of the Pacific, 1969; M.S. University of Arizona, 1975; Ph.D. University of Wisconsin, "Economics of Hog Production in Wisconsin, 1968–1977: A Farm Simulation Approach."
Rafael Posada, Ph.D. Purdue University, "The Impact of the High Yielding Varieties on the Import Requirements of the LDC's: The Case of Wheat."
Michael Robert Rahm, B.A. Loras College, 1975; M.S. 1978, Ph.D. Iowa State University, "An Economic Analysis of the Corn Production Efficiency at Iowa Farm Firms."
Carlos Sevilla, B.A. University of Hawaii, 1970; M.A. 1972, Ph.D. Stanford University, "A Microeconomic Study of Corn Production in Guatemala."
Charles Cameron Short, B.A. 1971, M.S. 1976, University of British Columbia; Ph.D. Iowa State University, "Groundwater Mining in the Ogallala Aquifer in Relation to Rising Energy Prices and Agricultural Production."
William D. Shurley, Ph.D. Purdue University, "Production, Marketing, and Storage Decisions under Risk for Cash-Grain and Crop-Hog Farms in West-Central Indiana."
Evelyn C. Spears, B.S. Arizona State University,

1970; M.S. Michigan State University, 1977; Ph.D. Texas A&M University, "An Economic Model for Planning Combination Small Stock-Cattle Herd Development: An Application to Edwards Plateau, Texas."

Kenneth Wayne Stockes, B.S. 1967, M.S. 1969, Texas Tech University; Ph.D. Texas A&M University, "Economics of Alternative Beef Genotypes and Cattle Management/Marketing Systems."

Thomas Steven Walter, B.S. Cornell University, 1970; M.S. University of Florida, 1975; Ph.D. Stanford University, "Decision Making by Farmers and by the National Agricultural Research Program on the Adoption and Development of Maize Varieties in El Salvador."

John Patrick Warren, B.S. Oklahoma State University, 1969; M.S. 1974, Ph.D. Texas A&M University, "The Texas Bay Shrimp Industry: A Description and Management Model."

Public Policy

Joyce Elaine Allen, B.S. North Carolina Agricultural and Technical University, 1974; M.S. North Carolina State University, 1976; Ph.D. University of Illinois, "An Analysis of the Food Stamp Program: Policy Decisions and Household Food Expenditure Patterns."

Edinaldo Gomes Bastos, B.A., M.A. University of Federal de Pernambuco; Ph.D. Cornell University, "Farming in the Brazilian Sertao: Social Organization and Economic Behavior."

Wu-Hsiung Chen, B.S. 1966, M.S. 1970, Chung-Hsing University; Ph.D. University of Illinois, "An Economic Study on Government Rice Stock Operation in Taiwan."

Albert Essel, B.S. University of Science and Technology, 1973; Ph.D. Iowa State University, "Estimated Impacts of a Land Set-Aside Policy on United States Agriculture in 1985: A Quadratic Programming Analysis."

J. R. Groenewegen, B.S. 1975, M.S. 1976, University of Guelph; Ph.D. University of Minnesota, "Corn and Soybean Acreage and Yield Response with Emphasis on Multiple Product Production, Uncertainty, and Commodity Programs."

Patricia Hutton, B.S.A. University of Manitoba, 1974; M.A., Ph.D. University of Wisconsin, "U.S. Dairy Policy: A Quantitative Analysis of the Post World War II Period."

Duane L. Marquis, B.S., M.S. University of Nebraska; Ph.D. Oklahoma State University, "Value of Improved Forecast Information from a Satellite-Based Crop Information System"

Eric A. Monke, B.A. 1974, Williams College; Ph.D. Stanford University, "Government Policy and International Trade in Rice."

William Palmer Patton, B.A. 1975, M.A. 1976, Texas Tech University; Ph.D. Texas A&M University, "The Impact of the 1977 Food and Agriculture Act on Cotton Production in the United States."

Anne Margaret Thomson, B.A. Cambridge University, England, 1972; Ph.D. Stanford University, "Nutrition, Food Demand and Policy."

Regional, Rural and Community Development

AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Ames, Iowa, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, James P. Houck, Department of Agricultural and Applied Economics, 332 Classroom Office Bldg., University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Ronald A. Schrimper, Department of Economics and Business, P. O. Box 5368, North Carolina State University, Raleigh, NC 27650

Effects of an Export Embargo on Related Goods: Logs and Lumber

A. Clark Wiseman and Roger A. Sedjo

This paper extends and applies the Marshallian derived demand model in the context of international trade. The model is utilized to derive estimates of the market equilibrium, net welfare, and welfare incidence effects of a hypothetical embargo of softwood log exports from the Pacific Coast region of the United States. The approach is potentially applicable to the analysis of various restrictions on primary products exports which may be instituted to maintain the viability of domestic processing industries.

Key words: export embargo, forest products trade, trade policy.

This paper estimates the efficiency and distributional effects of a hypothetical total embargo of softwood log exports from the Pacific Coast region (Washington, Oregon, and California). The issue is of considerable practical interest: restrictions, including an embargo on logs produced on federal lands in the region, have been in effect for more than ten years, and congressional hearings (U.S. Congress) periodically examine additional restriction options, including extending the scope of the embargo to logs from private lands. Discussions and analyses of the log export issue, including Haynes (1976) and Wiener, have yielded diverse opinions and estimates of present and potential effects, including conjecture on the extent of the "feedback" of increased foreign demand for processed domestic wood products resulting from foreclosure of the raw material source. In the following, limits to the extent of this potential feedback are identified and estimates of effects of log export prohibition are made for two limiting cases. Price and output effects and incidence of welfare impacts upon affected groups within the Pacific Coast region (PCR) are estimated for the two cases.

Paarlberg and Thompson have used a multiproduct partial equilibrium model to analyze the effect of a tariff when goods are related. However, the relationships in their model consist of nonzero cross-price elasticities of demand, rather than relatedness in production. Dardis carried out an analysis of gains from trade using a model that included an intermediate good and final product. The analysis did not employ an explicit derived demand model, and was limited to the small country (price taker) case. A small-country partial equilibrium model was also employed by Bautista in a study of effects of exchange rate changes on prices of a primary good and a processed commodity using the primary good as an input. Because fixed stocks of the goods were assumed, supply side impacts were not included in the analysis. The forest economics literature recognizes that the demand for logs is derived from the demand for lumber; however, an analysis that explicitly integrates the two markets is not available. Haynes, for example, deals only with the demand side of the markets and uses the "marketing margin" concept (Tomek and Robinson) as constituting a stumpage-lumber price spread (Haynes 1977).

The theoretical basis for the present analysis is an extension of Marshall's derived demand model under fixed factor proportions. The approach allows the simultaneous treatment of the primary (log) market and the market for the final product (lumber) and provides a straightforward means of assuring that consistency is maintained between markets. The methodology developed may be useful for analyzing the implications of other restrictions ostensibly designed to promote processing industries or to maintain low domestic final

---

The authors are, respectively, an associate professor of economics, Gonzaga University, and Senior Fellow, Resources for the Future.

This research was undertaken as part of the Forest Economics and Policy Program of Resources for the Future.

product prices. The principal focus of this analysis is upon efficiency and distributional implications. The model is extended to include estimates of the welfare incidence in terms of Marshallian surplus measures for three affected groups—owners of factors employed in the primary good industry (log production), owners of factors in the value-added or processing industry, and purchasers of the final product (lumber). Also, because of U.S. dominance in world softwood log markets, the analysis abandons the small country assumption of exogenous prices of both primary and final products.

In the next section, we briefly review current legal restrictions on U.S. log exports and describe the role of the Pacific Coast region (PCR) in log and lumber markets. Next, we illustrate the basic model and the theoretical effects of a log export embargo, then discuss the empirical application of the model. And, finally, we give results and draw conclusions.

Background

Since 1974, the U.S. government has prohibited the export of softwood logs from federally owned land (under U.S. Forest Service and Bureau of Land Management administration) west of the 100th meridian. Prior to that, from 1969 through 1973, the ban was partial, limiting log exports from federal lands to a maximum of 350 million board feet per year. As with other countries having similar restrictions, the basic intent of the legislation is to maintain a low price of the basic raw material input into the forest products industries, and, hence, protect domestic processors from the cost-increasing effect of log export trade.

The United States produces about 30% of the world's softwood saw and veneer logs, and is its major exporter of softwood logs, accounting for almost 50% of world exports. U.S. exports come almost exclusively from the PCR, where in recent years annual log exports have been about 2,500 million board feet, or 15%–20% of total PCR softwood log production. Over 95% of the PCR log exports go to East Asia, primarily to Japan and Korea. Exports of logs from the PCR to other U.S. regions are negligible.

Although the United States produces about 20% of the world's softwood lumber, its gross exports constitute only about 8% of total world exports. Indeed, the United States is a net importer of softwood lumber, its gross imports accounting for about 30% of the world's total. During the mid-1970s the PCR produced over 50% of the total U.S. production of softwood lumber. Only about 5% (about 800 million board feet in 1976) of the PCR lumber production was exported internationally. In 1976, about 25% of international softwood lumber exports of the PCR went to Japan, 12% to Canada, and the remainder to various other countries including almost 40% to western European countries. In addition, net regional "exports" to other areas of the United States constituted about 30% of the region's total lumber production.

The U.S. log export controls appear to have been a reaction to the large and rapidly growing volume of log exports to Japan, experienced in the 1960s. The percentage of the Washington and Oregon timber harvest going to Japan as logs rose every year between 1962 and 1970, going from about 2% to 16% over the period. The large growth in Japanese demand for wood resulted largely from a very high rate of economic growth in that country, accompanied by a prolonged housing boom. The tendency of the Japanese to rely heavily on log imports rather than on imported lumber reflected Japan's comparative advantage in labor-intensive, wood-processing activities augmented by Japanese trade policies directed toward the protection of the processing industries. In addition, the wide variety of specifications and widespread customization of lumber required by traditional Japanese construction methods do not readily lend themselves to lumber having U.S. standardized specifications.

A Log/Lumber Trade Model

In this analysis it is assumed that ordinates of the relevant supply and demand functions represent the private and social marginal rates of transformation in production and consumption, respectively. Accordingly, the conceptual model developed in this section will employ long-run supply and demand functions in the assumed absence of technological externalities. All estimates of elasticities used in empirical estimation in the next section are also long run, in order to avoid various short-run problems such as unemployment and excess capacity, capacity constraints, and inventory changes. "Processing" is an input which,

together with the homogenous raw material input, logs, is used to produce the finished homogenous product, lumber. It is assumed that both the composite input "processing" and the input "logs" are supplied by competitive industries subject to increasing costs, and that lumber production requires fixed proportions of the two inputs.

Let $l = a_1L$ and $r = a_2L$, where l is quantity of logs, L is quantity of lumber, r is quantity of processing and the a_i are input-output coefficients. For convenience, define an arbitrary quantity L_0 of lumber as a "unit," and the quantity a_iL_0 of the input as a "unit" of the input, so that a "unit of logs" and a "unit of processing" are defined as the respective amounts of the inputs required to produce a unit of lumber. This procedure allows a convenient diagrammatic representation of both the log and lumber markets simultaneously.[1]

In figure 1, D_L represents the PCR own-demand for lumber. Denote the "rest of world" (ROW) effective demand function for PCR lumber (not shown in figure) as D_L^F. This excess demand of other regions is "effective" in the sense of being net of transportation-related costs, tariffs, etc. Addition of D_L^F to D_L horizontally yields the function $D_L + D_L^F$, the total demand for PCR lumber.[2] Subtracting the processing supply function (not shown) vertically from $D_L + D_L^F$ gives D_l, the demand for PCR logs given the existence of lumber trade.

To illustrate, if the price of lumber is P_2, P_2e units of PCR lumber are demanded, of which de is export demand. The supply price (cost) of the processing industry at output P_2e is distance ve, so that at P_2 the demand price of the P_2e units of logs demanded is P_2 minus ve, or R_2.

The PCR supply function of logs is shown as S_l in figure 1. The vertical addition to this of the processing supply function gives S_L, the PCR supply curve of lumber given no log trade.[3] Denote the ROW effective demand function for PCR logs as D_l^F. Subtracting D_l^F horizontally from S_l gives $S_l - D_l^F$, the supply

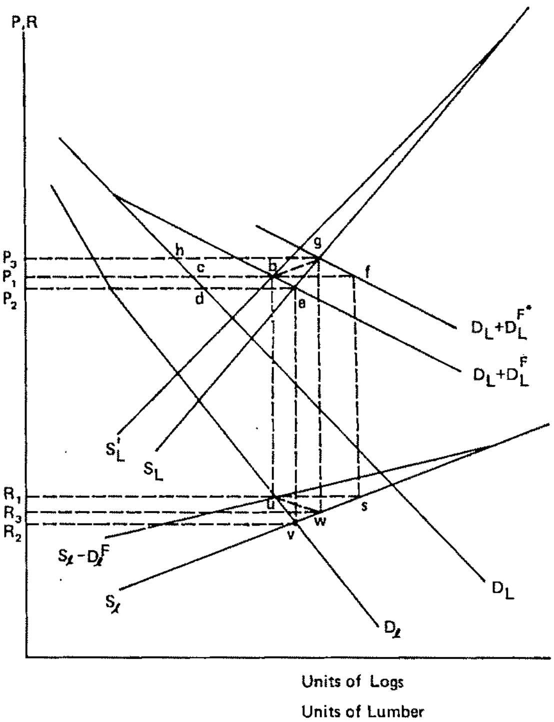

Figure 1. Market equilibrium and effects of log export embargo for a region exporting both logs and lumber

function of logs to the PCR, given the existence of log trade.[4] Addition of the supply function of processing vertically to $S_l - D_l^F$ yields S'_L, the PCR supply function of lumber, given trade in logs.

An "initial" equilibrium where the PCR is an exporter of both logs and lumber is depicted at prices P_1 and R_1. At the equilibrium log price R_1, production of logs is R_1s. Of this, su is exported and R_1u is processed in the PCR at cost ub; cb units of lumber are exported at price P_1, and P_1c consumed in PCR.

The effects of a total log export embargo by the PCR are also shown in figure 1. As a limiting case, it is first assumed that the ROW demand function D_L^F is not affected by log market changes. Later, a second limiting case is discussed which allows for feedback effects on the ROW lumber market resulting from the imposition of a log embargo.

Effects of Log Export Embargo: No Feedback in Lumber Market

In the case of no feedback of increased foreign demand for PCR lumber resulting from a log

[1] Gardner notes (p. 407) that the derived demand model under fixed factor proportions can be analyzed by graphical methods. The presentation employed here will be entirely diagrammatical.

[2] Were the region a net importer of lumber, the same basic derivation would apply, except that an ROW-effective lumber supply function would be subtracted from D_L to obtain total demand for PCR lumber.

[3] To avoid unnecessary graphical complications, the analogous derived demand for logs given no lumber trade is not shown; S_L is depicted because of its relevance in the later analysis.

[4] Continuing the point of note 2, appropriate modification of the same model could depict the case of a log-importing region.

export embargo, the embargo would result in an equilibrium in the PCR log market at the point v. All logs are processed at cost ve. As compared to the initial equilibrium, lumber exports increase to de units, and PCR consumption increases at the lower lumber price to P_2d. The loss of economic rent to producers of logs is equal to the area R_1svR_2, and the gain in buyers' surplus to buyers of PCR logs is R_1uvR_2. This surplus consists of gains to both buyers and processors of PCR lumber. The area P_1beP_2 is the consumers' surplus gain to lumber buyers, and it can be shown that the difference between R_1uvR_2 and P_1beP_2 represents the increase in producers' surplus (rent) of the processing industry. Of the lumber consumers' surplus, P_1cdP_2 is gain to PCR buyers, and the remaining area $cbed$ is the gain of ROW buyers.

In summary, if the ROW demand for PCR lumber is independent of log sales to the ROW, a log export embargo will reduce both the price of logs and lumber in the PCR. Welfare losses in the region will exceed the welfare gains by the sum of the areas uvs and $cbed$ in figure 1. Distributionally, the prohibition would result in losses to log producers and gains to domestic processors and buyers of lumber. Some of the total gain to buyers will accrue outside the PCR.

Effects of Log Export Embargo: Maximum Feedback in Lumber Market

If there is interdependence between ROW log and lumber markets, the effect of a log export ban would be an outward shift in D_L^F. The amount of the shift will determine the amount of the increase or decrease in lumber and log prices and will affect the magnitude of welfare effects. The shift could result from increases in residual lumber demands in the nonwestern United States and Japan. That is, it could be caused by the direct influence of the increased demand for PCR lumber by the former major log importer, Japan, or an increased demand for PCR lumber from other areas (primarily, the non-PCR United States) whose former lumber supply from Canada is partially diverted to Japan.

The maximum increase in demand for PCR lumber that could occur as a result of a log export embargo would be an increase equal to the equivalent amount of logs formerly exported to ROW.[5] This demand shift is shown in figure 1 by the function $D_L + D_L^{F^*}$ through the point f, where $bf = su$. The equilibrium in this case is at prices P_3 for lumber, R_3 for logs, and processing price equal to distance wg. In comparison with the earlier limiting case of no feedback, the decline in log price is less, and lumber price rises rather than falls.

The distributional impact in this case also may be analyzed, where again the comparison is with the initial situation. The loss to owners of resources employed in log production is R_1swR_3. The gain to owners of resources employed in the processing industry is R_1uwR_3 plus P_1bgP_3.[6] These two areas represent, respectively, the gains to the processing industry from purchasing more logs at a lower price and from selling more lumber at a higher price. The loss to consumers in the PCR is P_1chP_3. The imposition of the log export ban in this case may result in a net welfare gain for the region, the net gain illustrated in figure 1 being $hgbc$ minus usw.[7]

The general theoretical results in the limiting cases may be summarized as follows. For any feasible theoretical feedback effect, the price and production of logs will fall, and owners of resources in log production will sustain losses. The reverse will be true for the processing industry which experiences gains in both limiting cases. Regional buyers will gain or lose, depending on the potential price-increasing impact of the feedback effect on lumber demand. The region as a whole may realize a net welfare gain or loss, depending upon the size of this feedback.

Empirical Analysis

Table 1 gives the estimated elasticities that were used in calculating market changes and

[5] This result can be demonstrated by a modification of the present model representing the production, trade, and consumption equilibrium of a region, i.e., Japan, that is both a log and lumber importer. Foreclosing the region's supply of logs from PCR will shift the region's excess demand function for lumber horizontally outward by the equivalent amount of logs formerly imported. Realistically, the shift in foreign demand facing each of the several lumber-exporting regions will be less than this total shift. The text takes as one limiting case (equivalent to the two-country case) that where the entire "feedback" effect of the embargo is upon the PCR.

[6] It can be shown that the segment bg is a portion of the processing supply function shifted vertically by the constant R_1.

[7] A net domestic welfare increase as a result of intervention with free trade is a theoretical possibility when the intervention has a terms-of-trade effect.

Table 1. Elasticity Estimates Used in Calculating Effects of Log Export Embargo

Function	Base Elasticity	Alternative Elasticity
D_L	−.35	−1.00
S_L	.44	1.00
S_l	.21	.48
D_L^F	−15.45	−9.19
$D_L + D_L^F$	−3.52	−40.00
D_l	−1.09	−2.16
Processing supply	4.23	5.50

welfare effects resulting from an export ban. In addition to the base estimates, an alternative was considered in order to examine the sensitivity of the results to different elasticity estimates. The base elasticities of D_L and S_L are long-run estimates developed by the U.S. Forest Service (USFS) for its "Timber Assessment Model" (U.S. Forest Service Pacific Northwest Forest and Range Experiment Station). The alternative values of D_L and S_L—both unity—are based on Haynes' (1976, p. 7) summary statements regarding earlier estimates. It should be noted that the base estimates are derived from a more recent and comprehensive analysis than those underlying the alternative estimates. All other elasticities were calculated by utilizing the USFS estimates, constraints imposed by the model itself, and other data on price and quantity relationships.[8] Because all but two of the functions in figure 1, D_L and S_l, are derived from others, even a limited knowledge of elasticities, along with market prices and quantities, allows calculation of required values of all other elasticities.

For example, it can be shown that for a given level of output,

$$ES_p = \alpha \bigg/ \left(\frac{1}{ES_L} - \frac{(1-\alpha)}{ES_l}\right),$$

where ES_p, ES_L, and ES_l are elasticities of supply of processing, lumber, and logs, respectively, and α is value added of processing per unit of lumber. Therefore, an estimate of the value of two of the elasticities and the processing margin, α, is sufficient to yield an estimate of the other elasticity. A similar relation holds on the demand side.

It was not necessary to estimate the elasticity of $S_l - D_l^F$. Under a log export embargo, equilibrium in the log market occurs at a point on S_l determined by lumber market conditions. The function $S_l - D_l^F$ together with S_l theoretically determine the disposition of PCR log production between exports and domestic processing (points s and u in fig. 1). However, in the actual estimation, market price, production, and export data were utilized to obtain points s and u.

The data base utilized in obtaining empirical estimates is from 1976, a year during which we assume the effect of the existing restrictions on log exports to be small. Accordingly, the data are assumed to reflect a regime free of effective log export restrictions. Actual data on prices and quantities and the information in table 1 are sufficient to generate consistent estimates of price and quantity changes for both logs and lumber, as well as welfare gains and losses to various groups in the limiting cases of maximum feedback effect and no feedback effect. Linear forms were assumed for all functions over the range of values analyzed. Details of calculation are not elaborated here.

Results and Conclusions

Estimates of the market equilibrium effects are given in table 2 and the corresponding welfare effects in table 3. The predicted changes in lumber price in the two cases are quite small, both in an absolute sense and relative to the log price changes. This result is interesting because the restrictionist argument is that the prohibition of log exports would result in a substantial reduction of lumber prices within the United States. Indeed, depending upon the degree of feedback, export restrictions actually may increase domestic lumber prices. In either case, domestic lumber sales would be affected only slightly.

Notice that both limiting cases yield a net regional welfare loss. The owners of resources devoted to log output will experience substantial net losses, given any feasible feedback, while owners of resources engaged in processing will experience substantial net gains. The size of these gains is relatively insensitive to the degree of feedback. Since purchasers of

[8] Data sources were Bergvall, Bullington, Gee (1976); Haynes (1976); Howard and Hiserote; Ruderman; U.S. Bureau of the Census; U.S. Department of Agriculture. No extraneous estimate of the elasticity of D_L^F is available. It was calculated on the assumption that ROW own-lumber demand and supply elasticities have the same values as those estimated for the PCR.

Note: See table 2 note.

lumber may experience either gains or losses depending upon the feedback effect, the results provide a dilemma for proponents of a restriction intended to maintain low lumber and regional housing prices. If an export ban results in a gain to regional lumber users (small feedback), there will be a substantial net welfare loss. On the other hand, if the regional resource misallocation cost is small, there is a loss to regional lumber users. Finally, the findings indicate that the net welfare effect for the Pacific Coast region is directly related to the effect on the log production industry and opposite to that experienced in the processing industry.

Farm Size Evaluation in the El Paso Valley: A Survival/Success Approach

James W. Richardson and Gary D. Condra

Policy makers and agricultural economists in the United States have long been interested in the effects of size on farm survival and success. Most farm size studies to date have concentrated on economic efficiency and have failed to incorporate the effects of uncertainty, time, income taxes, financial considerations, and variation in year-to-year net cash flows on the survival/success of different size farms. A dynamic Monte-Carlo simulation-programming model was developed and used to analyze the projected survival/success of four alternative farm sizes for the El Paso Valley. For farms in the El Paso Valley, the projected chances of survival and success increase as farm size increases from 160 to 960 acres and/or beginning equity level increases from 25% to 100%.

Key words: farm size, farm survival, irrigation project, 160-acre limitation, simulation-programming.

Policy makers and agricultural economists in the United States have long been interested in the effects of size on farm survival and success. However, the current controversy about enforcement of the 160-acre limitation of the Reclamation Act of 1902 stimulated new efforts to identify and quantify these effects (e.g., Seckler and Young; Hall and LeVeen). This limitation would permit a farmer to own no more than 160 acres (320 acres with a spouse) of land irrigated from a Bureau of Reclamation project. Many arguments have been presented for and against this limitation on farm size. However, it is not the purpose of this paper to restate these arguments. Instead, it is to provide projections to the effects of size on farm survival and success.

The El Paso Valley was selected for study because it would be affected by enforcement of the 160-acre limitation more than any other area in Texas. Approximately 100% of the farmland in this valley is irrigated with Bureau of Reclamation water supplied from the Rio Grande Project. This area, located in the far western tip of Texas, receives less than 10 inches of rainfall annually. Thus irrigation is required for production of all crops, principally cotton, alfalfa, grain, pecans, and vegetables. Ground water is available as a secondary irrigation source.

Methodology

The need to incorporate uncertainty in studies of farm size has been pointed out by Heady (pp. 500–34), Olson, Raup (1969, 1978), and Madden and Partenheimer. Failure to account for uncertainty in farm size studies may cause the researcher to identify incorrectly the true long-run average cost curve and the most efficient farm size. For example, if uncertainty increases across farm size, the long-run average cost (LAC) curve will be shifted up and to the left, reducing the size of farm associated with minimum LAC.

Olson and Raup (1969, 1978) noted that most farm size studies have been static, i.e., for a single time period. These static studies did not account for year-to-year management problems, such as increasing costs of inputs, changing land values, changes in productivity, variation in crop prices and yields, and changing financial conditions. If these year-to-year factors increase the average total cost of production equally across all farm sizes, the same

Technical Article TA-15378 of the Texas Agricultural Experiment Station.

The authors gratefully acknowledge the comments and suggestions of Bruce Beattie, Bruce Gardner, Richard Shumway, and the anonymous *Journal* reviewers.

size would be optimal in both static and dynamic analyses. However, it seems unlikely that increased costs affect different size farms equally.

The effects on farm size of income taxes, financial considerations (debt refinancing, interest received on cash reserves, etc.), and variation in year-to-year net cash flows, generally have been ignored. Madden and Partenheimer, Raup (1969, 1978), and Olson suggested incorporating these factors because they influence the shape of the LAC curve. For example, existing income tax laws may provide added economies-of-size for farms large enough to qualify for special tax provisions.

Raup (1969) also wrote that the primary question farm size studies should address is: What size of farm is most likely to survive? Because the relationship between economic success (or viability) of farms in a dynamic, uncertain environment and economic efficiency in the static case has not been clearly established, farm management and policy decisions based solely on short-run economic efficiency could result in farm sizes that are economically unsuccessful in the long run.

One of the few farm size studies that has addressed the question of viability over a multiple-year planning period was done by Holland and Young. The economic viability of alternative farm sizes in the Columbia River Basin was evaluated using a deterministic model to simulate representative farms over a fifteen-year planning horizon. The simulation model computed annual after-tax net returns available for family living expenses. Costs and yields used in the model were based on representative management practices and current technology. Crop prices were held constant. Holland and Young evaluated the viability of various farm sizes at current and preproject land prices. In their study, (*a*) economic viability was used to address the question of optimal farm size, (*b*) a dynamic simulation technique was employed, (*c*) the traditional economic accounting approach was compared to an after-tax cash flow approach, and (*d*) the importance of land prices on the viability of a farm was analyzed. Still, this analysis did not account for the uncertainty of agricultural production and marketing. In addition, the study did not consider financial aspects of operating a farm, such as refinancing debts during periods of low income, accelerated debt repayment, the receipt of interest on cash reserves, and the effect of different beginning equity levels on a farm's survival.

Description of the Model

The model used for this study incorporates uncertainty in production and marketing activities over time. This was accomplished with a dynamic farm simulation-linear programming model. Several farm simulation models were available to analyze alternative farm sizes (e.g., Hardin, Held, Condra, and Hutton and Hinman). A modified version of the capital investment simulation model developed by Hardin was selected because it can simulate the annual production, marketing, financial, and income tax activities of a farm over a multiple-year planning horizon.

The programming-simulation model begins each year of the planning horizon by determining the farm's crop mix. A linear programming (LP) model is linked to the simulation model to permit the crop mix to change over time. The LP model maximizes the farm's expected net returns above variable costs, subject to constraints reflecting acreage allotments for pima cotton and rotation patterns.[1] This procedure has been used previously by Chien and Bradford and by Condra. Total variable production costs are calculated by multiplying variable costs of production per acre by planted acreages of the respective crops and summing over all crops. Crop prices and yields are drawn randomly from user-specified probability distributions. Total cash receipts are estimated as the product of harvested acreage, yield, and price summed over all crop enterprises.

The simulation model depreciates from machinery and depreciable items attached to the land (buildings, irrigation equipment, etc.), using either the straight-line or double-declining balance method. Farm machinery is replaced on a user-specified, replacement-purchase schedule with equipment loans ob-

[1] An adaptive expectations model was used to develop expected net returns per acre for the enterprises (Y_t^*). This approach has been shown by Fisher and Tanner to describe reasonably the process used by farmers to develop price and yield expectations. The basic model proposed by Nerlove is $Y^*_t = Y^*_{t-1} + \alpha(Y_{t-1} - Y^*_{t-1})$, where Y^*_{t-1} is the expected net return per acre in year $t-1$, Y_{t-1} is the actual net returns, and α is the coefficient of expectations. It is assumed that the coefficient of expectations equals 0.5. Expected net returns are a geometrically weighted average of past net returns. By using 0.5 for α, the variance of net returns is equivalent to a three-year moving average of net returns (Hillier and Lieberman).

tained as needed. Other production expenses, fixed costs, and family cash withdrawals are calculated each year based on the cost of these items in year 1 and their assumed annual inflation rates of 7% to 8%. Interest and principal payments for long-term and intermediate-term debts are based on the value of the original debt and a specified amoritization schedule. Income taxes for the farm operator are calculated using schedule Y for married individuals filing jointly. The income tax liability is adjusted for eligible investment tax credits and tax on capital gain.

Ending-year, after-tax, net cash income is calculated as total cash receipts less variable production costs, cash rents, fixed and other production expenses, principal and interest payments on outstanding debts, downpayments for machinery purchases, income taxes, and family cash withdrawals. Net farm income and other output variables are calculated at the end of each year. If after-tax net cash income is negative, the model meets the cash flow deficit by drawing on the farm's cash reserve or by refinancing its assets. A farm is considered to be insolvent if it is unable to meet annual net cash-flow deficits by borrowing against its equity in farmland and machinery. The creditworthiness of a farm is determined in each year of the ten-year planning horizon using the calculated ratio of equity to assets. If a farm has an equity ratio less than a user-specified minimum, it is declared insolvent

The ending-year value of owned farmland is calculated by inflating beginning-year land values by the annual inflation rate for farmland. Ending-year liabilities are calculated as beginning-year liabilities adjusted for principal payments, purchases of new farm machinery, and debt acquired from financing cash flow deficits. Ending-year cash reserves, liabilities, and assets are used as beginning-year values in the next year of the planning horizon. Thus the model is recursive.

Since the simulation model is essentially a cash flow simulator, validation is much simpler than if it were a behavorial model of farm growth. The model was validated by verifying each equation in the computer program for different deterministic runs. The LP model was validated independently and in conjunction with the simulator to insure overall validity. The average cropping patterns developed by the LP model were reviewed for realism by extension personnel and farm operators in the El Paso area. Further analysis showed that the LP model exhibited increased variability of cropping patterns; however, there is no significant difference in farm survival between the LP crop mix and a crop mix held constant at the levels observed for representative area farms.

Because the programming-simulation model replicates a multiple-year planning horizon a large number of times, it provides much information on both an annual and a summary basis. On an annual basis, data necessary to calculate experimental probability density functions (PDFs) is generated for each endogenous variable—cash receipts, production costs, income taxes paid, interest paid, depreciation, ending-year net after-tax cash flows, total assets, total liabilities, net worth, equity ratio, and cropping patterns. The expected performance of various size farms can be compared for each year of the planning horizon using the PDFs for after-tax net cash flows and the equity ratio.

The model also provides several summary statistics. One of the most useful is the cumulative probability distribution (CPD) showing the survival probability of a given farm. Survival is synonomous to solvency in this analysis. By comparing the CPD of survival for different farm sizes, one can determine which farm size has the best chance of surviving for a given number of years. Because each year-ending financial situation is the beginning financial situation for the next year, the probability of survival tends to decrease over the planning horizon.

A second summary statistic is the net present value CPD. The CPDs for net present value can be compared across sizes to determine which offers the highest probability of economic success. A farm was considered to be an economic success if it provided the owner a rate of return greater than or equal to the after-tax discount rate, i.e., a positive net present value. (An after-tax discount rate of 7.5% was used based on annual interest rates in the area of 10% and a marginal tax rate of 25%.)

Application of the Model

Four alternative farm sizes (160, 320, 640, and 960 acres) were evaluated for the El Paso Valley. Data on representative irrigated farms were developed from both primary and sec-

ondary sources. Information obtained from the Bureau of Reclamation and interviews with farmers was used to verify published values for production costs, machinery complements, average farmland values, and average crop prices and yields.

Sensitivity of these results was tested by analyzing three alternative beginning equity levels (25%, 50%, and 100%) and three land tenure situations (full ownership, combined ownership-lease, and full lease). These beginning equity levels were selected to represent farms in three different situations: (*a*) beginning farmers with a minimum amount of equity (25%), (*b*) commercial farmers using debt financing to expand existing operations (50%), and (*c*) farmers with full equity choosing not to expand via debt financing (100%). The minimum equity ratio for determining solvency was set at 20%.

A ten-year planning horizon was simulated recursively 100 times for each situation to generate probabilities of success and survival. In each iteration, the LP model was used to select acreage levels for crops annually over the ten-year planning horizon. A separate LP tableau was developed for each farm size based on the farm's available labor, cropland, operating capital, pima cotton allotment, and existing cropping patterns. Constraints on the cropping patterns reflected differences in equipment requirements and risk-bearing ability as determined by farm survey data. Because of high per acre production costs and price variability, noncontract vegetable (onions and lettuce) and alfalfa production was generally not observed on 160- and 320-acre farms. The primary difference in the LP tableaus from one farm size to the next was the mix of crops. All four farm sizes were allowed to grow cotton. Smaller farms (160- and 320-acres) were not allowed to grow noncontract vegetables or alfalfa. The larger farms (640- and 960-acres) could grow alfalfa, and the 960-acre farms could grow up to 48 acres of noncontract vegetables.

Constraining cropping patterns in this way narrows the question addressed by this study to some extent. It may be that significantly larger acreages of noncontract vegetables, pecans, and other high-value crops could be produced. However, this would involve substantial changes in marketing conditions and facilities in this area. Therefore, this study does not assess the possible effects of a large-scale shift to higher-value crops upon the economic survival and/or success of a given size farm. While this is a relevant question, it involves a change in market structure of sufficient magnitude to place it beyond the scope of this paper.

To incorporate production and marketing uncertainties, annual values for crop prices and yields and water allotments were drawn at random from empirical probability distributions. Deviations from trend over the 1960–77 period and mean crop prices and yields (trended at 7% and 1%, respectively) were used to develop these empirical probability distributions over the ten-year planning horizon. (This procedure was suggested by Luttrell and Gilbert.) Stochastic prices and yields were appropriately correlated, based on their historical correlation coefficients.[2] Stochastic water allotments were used in the LP model to reflect availability of water from the irrigation project and to determine required pumpage of irrigation water. Target prices for cotton and small grains were used when stochastic prices were less than target prices.

The average variable cost of production for each crop was developed from farmer interviews and budgets prepared by the Texas Agricultural Extension Service and the Department of Agricultural Economics at New Mexico State University.[3] Fixed costs for each farm size (i.e., property taxes, Bureau of Reclamation water charges, legal and accounting fees, and liability insurance) were developed from farm interviews. Family living expenses were treated as a fixed, non-tax deductible annual expense. While a constant family living expense may overstate cash withdrawals during periods of low cash flows, interviews indicated that farmers maintained about the same standard of living in recent years despite considerable variation in cash flows. An opportunity cost for owner-operator labor ($11,800 per year) and a standard management fee ($20 per acre) were used to de-

[2] Prices and yields were correlated by multiplying the square root of the correlation matrix for prices and yields by a vector of standard normal deviates. The product was transformed to a unit scale (0 to 1) by integrating the appropriate area under a standard normal distribution. These resulting values were mapped into the appropriate empirical probability distributions for crop prices and yields using a table look-up function. This procedure has since been described and used by King (pp. 207–39).

[3] The interview results indicated that there was more variation in per acre variable costs within a given farm size than across farm sizes. This is consistent with earlier farm size studies reviewed by Olson and by Madden and Partenheimer. Therefore, the average variable costs of production across farm sizes were used as the variable cost of production for all four farm sizes.

velop the family living expense values for the different size farms.

Representative farm machinery complements for the four farm sizes were based on engineering data and interviews with farmers. Machinery was valued at existing costs for new machinery. It was assumed that a farm would replace one-tenth of its farm machinery each year, maintaining its initial complement over time. The assumed per acre machinery investments in year 1 were $575, $636, $580, and $544 for the 160-, 320-, 640-, and 960-acre farms, respectively. The 320-acre farm had the highest per acre investment in machinery because it is just large enough to justify owning some equipment that a smaller farm would lease (e.g., a cotton picker) but not large enough to spread the investment to per acre levels observed for the 640-acre farm.

Farmland value was assumed to appreciate at 10% annually, while the value of capital improvements and new machinery was increased at 5% and 8% per year, respectively. Used equipment value was assumed to increase at 4% per year. Average variable production, harvest, and fixed costs were assumed to increase at 8% per year. Family living expense was assumed to increase at 7% per year to maintain the family's initial purchasing power. Crop prices and yields were assumed to increase at 7% and 1% per year, respectively, over the planning horizon.

Results

Average cropping patterns for the ten-year period are shown in table 1 for each farm size These plans were generated by the LP model Since variable production costs per acre were held constant across farm size for each crop, variations in proportional cropping patterns between farm sizes can be attributed to the following restrictions in the LP model: (*a*) alfalfa was not grown on the 160- and 320-acre farms because of machinery requirements and (*b*) noncontract vegetables were grown on only the 960-acre farm. While these assumptions are consistent with practices in the area and sound farm planning principles, it should be recognized that these cropping patterns are not normative in the traditional LP sense.

The results from this study, presented in the following tables, are arranged by farm size, beginning equity ratio, and tenure situation. Farm size refers to total acres farmed. Beginning equity ratio is designated by a Roman numeral, where I signifies 50% beginning equity and II signifies 100% beginning equity. Tenure situation is represented by letters: A signifies 320 acres of land cash-leased with the remainder owned; B signifies all owned land. For example, I-A represents a farmer with 50% beginning equity, 320 acres cash-leased, and the remainder of the land fully owned. With the 640-acre farm, the owned acreage is 320 acres and 320 acres are cash-leased.

The 25% beginning equity level and total cash lease situations were analyzed, but the results are not presented because neither situation provided a significant chance of survival. With only 25% beginning equity, the farms were over-leveraged. With straight cash-lease farms, appreciation in land value was not available to the operator to improve his credit capacity over time. Insolvencies in these situations generally occurred before the fifth year in the planning horizon because annual net cash flow deficits greatly exceeded the farm's capacity to refinance them.

The projected chance of survival (i.e., remaining solvent) over the next ten-year period

	Chance of Survival			
	I-A[a]	I-B[b]	II-A[c]	II-B[d]
Farm size (Acres)	(%)			
160		1		100
320		14		100
640	5	88	100	100
960	90	100	100	100

Note: Survival is defined as having an equity ratio greater than 20%.

[a] 50% beginning equity, 320 acres cash-leased, remainder owned.
[b] 50% beginning equity, all owned land.
[c] 100% beginning equity, 320 acres cash-leased, remainder owned.
[d] 100% beginning equity, all owned land.

is shown in table 2 for the selected sizes of farms under alternative situations in the El Paso Valley. The 160- and 320-acre farms had a 100% chance of survival under situation II-B. However, in the 50% beginning equity situation (I-B), the chance of survival was projected to be very low. The 640-acre farm had a relatively high chance of survival under all situations except the 50% beginning equity with combined ownership and cash land lease (I-A). The 960-acre farm had a relatively high chance of survival under all four situations.

For a given beginning equity ratio and ownership situation, the chance of survival generally increased with farm size. The chance of survival also increased directly with the beginning equity ratio for a given farm size and ownership situation. This is because farms with a high beginning equity ratio have greater capacity to refinance net cash flow deficits during bad years. In addition, larger farms benefited more from appreciation in farmland values than smaller farms. This provided a relatively high proportion of the net worth increase over the ten-year period.

The projected chance of survival for a given number of years is shown in table 3. These results show that the 160-acre farm with 50% beginning equity (I-B) had only an 18% probability of surviving for five years. The 320-acre farm (I-B) had a much higher probability of surviving for five years, but only a 27% greater probability of surviving for seven years. The 640-acre farm combining ownership with lease of land and 50% beginning equity (I-A) had a

[b] 50% beginning equity, all owned land.

survival pattern very similar to the 160-acre farm (I-B); but, when full ownership of land was considered (640-acres, I-B), the chances of survival for a given number of years remained high. In fact, the 640-acre farm (I-B) which survived for six years had only about a 10% probability of failure in the last four years of the period.

Table 4 shows the chance of success (i.e., a net present value greater than or equal to zero) for the selected farm sizes and situations. No significant chance of success was projected for

160		0		0
320		0		6
640	0	0	11	80
960	14	44	94	100

Note: Success is defined as having a new present value greater than or equal to zero.
[a] 50% beginning equity, 320 acres cash-leased, remainder owned.
[b] 50% beginning equity, all owned land.
[c] 100% beginning equity, 320 acres cash-leased, remainder owned.
[d] 100% beginning equity, all owned land.

the 160- and 320-acre farms under any situation. The 640-acre farm had a significant chance of success in only one case, 100% beginning equity and ownership of all the farmland (II-B). The 960-acre farm had a high chance of success under the 100% equity situation; however, the chance of success was less than 50% for both situations with lower beginning equities (I-A and I-B). As in the case of survival, the chance of success increased directly with farm size and beginning equity ratio.

These results seem to support the hypothesis that larger farms in the El Paso Valley are more economically viable. However, the increased chance of survival and success does not depend on the operational characteristics of larger versus smaller farms. Instead, the larger farms had (*a*) lower management cost per acre and (*b*) a larger land asset base to appreciate over time.

The relationship between tenure situations (full ownership versus owner-cash lease) and the chance of survival and success is less consistent than that with farm size and beginning equity. The comparison of tenure situations can be made (*a*) between the same size farms with different tenure situations, or (*b*) between farms with the same owned acreage. The first comparison for a 640-acre farm with 50% beginning equity (640 acres, I-B versus 640 acres I-A) indicates that going from full ownership to an owner-cash lease situation decreased the chance of survival from 88% to 5% (table 2). However, the second comparison for a farm with 640 acres owned and a beginning equity of 50% (640 acres, I-B versus 960 acres, I-A) indicated that the owner-cash lease tenure situation increased the chance of survival from 88% to 90%. This inconsistency for tenure situations also exists for chances of success (table 4). Therefore, it can be said only that for a given size of farm, the chances of survival and success are higher if all the land is owned. Analysis revealed that land value appreciation played a major role in providing increased net worth which, in turn strongly increased the chance of survival. The cash lessee received no benefit from increased land values, whereas the land owner received a benefit in increased borrowing capacity.

Conclusions and Implications

First, there is a well-defined, direct relationship between farm size and/or beginning equity level and the chances of survival and success for farms in the El Paso Valley. This relationship is consistent throughout the results, covering a range of farm sizes from 160 acres to 960 acres. The results also suggest that this relationship probably extends beyond the 960-acre farm size.

The second major conclusion is that a straight cash-lease farm operation has little chance of survival and success. Cash-lease as a traditional growth strategy for young farmers does not appear to hold great promise in the El Paso Valley. The results show that a farmer needs to have at least 50% beginning equity in 640 acres of owned land before cash lease of 320 acres can be expected to improve the chance of survival and success.

The third conclusion is that the minimum size and beginning equity situation that will provide a reasonable chance of survival and success in the El Paso Valley for the next ten years is 100% beginning equity in 640 acres of owned farmland. "Reasonable chance" in this case is a 50–50 or greater chance of achieving both objectives, survival and success. This is not to say that a smaller farm and/or a lower beginning equity level cannot survive or succeed. However, a farm with less than the minimum situation (640 acres owned with 100% beginning equity) likely will not survive the next ten years. If it survives, its financial situation probably will deteriorate over that period. In this setting, the farmer will not replace worn-out equipment or practice conservation practices requiring capital investment. He will simple deplete his equity. This farm likely will not generate the required capital for growth. In the context of this study, growth to a larger size or a sizable beginning equity level is the only way to achieve a reasonable chance of success.

The capital requirement for a fully owned 640-acre farm, with 100% equity was assumed to be $1,651,000. Given that this is the net worth the farmer must start with to achieve a reasonable chance of survival and success, it is hard to see how young people will be able to enter farming in the El Paso Valley.

Much of the current interest in minimum viable farm size comes from the 160-acre limitation controversy. These results suggest that the minimum viable size for a commercial farm in the El Paso Valley is 640 acres or larger. If this is true, limiting acreage to less than 640 acres probably would not accomplish the policy objective of encouraging smaller,

family-owned farms. Instead, it would restrict farms to sizes which have little chance of survival and economic success, unless major changes occur in the Valley's production patterns.

Hall and LeVeen have argued that restricting the size of farms to a smaller than an economically viable size would result in reduced land values which, in turn, would restore economically viable agricultural production at a smaller size. Maybe such a process would occur in the El Paso Valley. However, it seems more likely that the long-run effects would be to increase the cost of holding land for suburban development and thus hasten the conversion of land to nonagricultural uses.

The major policy implication of this study is that enforcement of the existing 160-acre limitation in the El Paso Valley would restrict farms to a nonviable size. However, enforcement of the acreage limitation currently being considered by Congress, 960 acres per farming unit, would not be a barrier to the development of economically viable size farms in the Valley. While the results of this study may not be readily transferrable to other Bureau of Reclamation projects, the methodology can be used to determine the minimum viable farm size for other irrigation districts in the West.

Return Flow Control Policy and Income Distribution among Irrigators

Daniel J. Dudek and Gerald L. Horner

Income distributional impacts and irrigation return flows resulting from the implementation of alternative water quality policies were projected for the Western San Joaquin Subbasin from a recursive simulation of an integrated physical-economic analytical system. The imposition of a water management policy to increase irrigation efficiency resulted in an improved income distribution with a slight decline in average firm income. Salt load and concentrations were reduced by 80%. A policy of increased surface water costs worsened income distribution and decreased average firm income by 34%. Total salt load decreased by 35%, but the concentration in return flows was only slightly decreased.

Key words: income distribution, irrigation return flows, salinity, water management, water pricing.

While economics is concerned with economic well-being as described in terms of both efficiency and equity, public and academic economists seem preoccupied with the efficiency criterion in policy analysis, particularly with respect to natural resources. Explicit attention to equity or the distributional impacts of policy have been subsumed in the estimation of aggregate benefits and costs irrespective of distribution. While it is true that distributional analysis is hampered by a lack of precision in the specification of equity criteria, we argue that such analysis should occupy a more critical role in policy evaluation. In particular, distributional analysis, whether of income or wealth, is a comprehensive socioeconomic evaluation of public policy that delineates who benefits and who pays. Such analysis has implications as well for the need for and design of compensating programs such as cost sharing. Distributional analysis also may indicate the existence of synergistic and/or antagonistic effects between proposed and operating policies and programs. Recognizing the crucial policy role such analysis may occupy, it is our intent to demonstrate its significance in an empirical context. Thus, this paper reports the income distributional impacts within a San Joaquin Valley irrigation district from the implementation of two alternative water quality policies to manage irrigation return flows.

Several empirical approaches can be applied in assessing the distributional impacts of natural resource policy. The basic underlying contention is that the institutional environment defining property rights in resources and public policy directed toward those resources affects the distribution of income. Distributional effects, whether resulting from the direct application of economic incentives in the form of taxes or subsidies or resulting indirectly from restrictions on resource supply or use, may be represented by a single index number such as the Gini coefficient (Hansen and Schwartz), as net impacts upon classified groups (Collins), or as an estimated function for the Lorenz curve itself. Each of these approaches has merit. In this analysis, both the Gini coefficient and gross impact by income group are used to represent the income distribution resulting from each alternative policy. Despite the fact that a unique correspondence between Gini coefficients and income

distributions does not exist, they are useful comparative summary measures of distributional impacts.

The Federal Water Pollution Control Act Amendments of 1972 (PL 92-500) outline broad water quality goals for the nation and establish mandates for each state to control point and nonpoint sources of pollution from all man-made activities. Pollution from irrigation return flows was originally classified as a point source and thus subject to the National Pollution Disposal Elimination System Permit Program. However, in 1977 the Clean Water Act (PL 95-217) reclassified irrigation return flows as a nonpoint source and, as such, subject to the procedures outlined in Section 208 of PL 92-500. Section 208 requires that nonpoint sources of pollution be identified and that procedures for control be specified as "Best Management Practices" (BMP). The specification of BMPs and a schedule for implementation are to be a part of the Areawide Waste Treatment Management Plans which must be submitted to the Environmental Protection Agency (EPA). Section 303 of PL 92-500 requires that the state adopt a continuing planning process that is consistent with all provisions of the Act. This process is designed to insure that the initial plan formulated under Section 208 remains effective under changing economic and environmental conditions. In addition to its planning responsibility, each state must prepare an estimate of (*a*) the environmental impact, (*b*) the economic and social costs necessary to achieve the objectives of the act, and (*c*) the economic and social benefits.

Determining the distribution of benefits and costs by socioeconomic or geographic group resulting from specific BMPs is an important criterion in evaluating a Section 208 plan. Two policies that could be specified as BMPs to reduce irrigation return flows in the San Joaquin Valley were evaluated for changes in water quality and income distribution. These policies are (*a*) to increase the price of irrigation water supplied from surface developments and (*b*) to alter water management practices so as to attain a targeted 30% efficiency increase. These policies were evaluated by simulating farmers' decisions and estimating irrigation return flows using data from the Cen-melons are the principal crops grown on the 145,000 irrigated acres comprising the District. Farmers in the district used an average of 3.82 acre-feet of irrigation water per acre in 1976. Water costs to the farmer included a fixed assessment of $2.15 per irrigated acre and a variable charge of $2.50 per acre-foot of water delivered. Approximately 15% of the District's water supply is groundwater. Surface and subsurface irrigation return flows are collected and disposed in the San Joaquin River.

Methodology

The alternative water quality policies were evaluated with the integrated land and water resource analytical system presented in figure 1. Specific policy impacts were estimated in the water quality subsystem. Its principal analytical components consist of two location-specific models sequentially linked to simulate spatial and temporal changes in agricultural production and water quality. Each model contains 126 subregions encompassing 2.78 million acres in the San Joaquin Subbasin. These subregions were defined such that the soils comprising each are homogenous with respect to yield characteristics, response to fertilizer, management, and land treatment measures. These subregions range in size from 1,498 to 78,711 acres, with a mean size of 22,081 acres.

Production Model

The linear programming model derives optimal cropping patterns, water, and fertilizer use for each subregion or cell. The specification of alternative cultural practices for each cell allows the estimation of spatial and temporal changes in agricultural production and return flows as a result of changes in policies. The model is segmented into regional activities and cell-specific (subregional) activities. Regional activities include crop production and commodity marketing. These activities are aggregate since sufficient differences do not exist in either market prices or production costs (other than irrigation and land costs) among the cells of the study area.

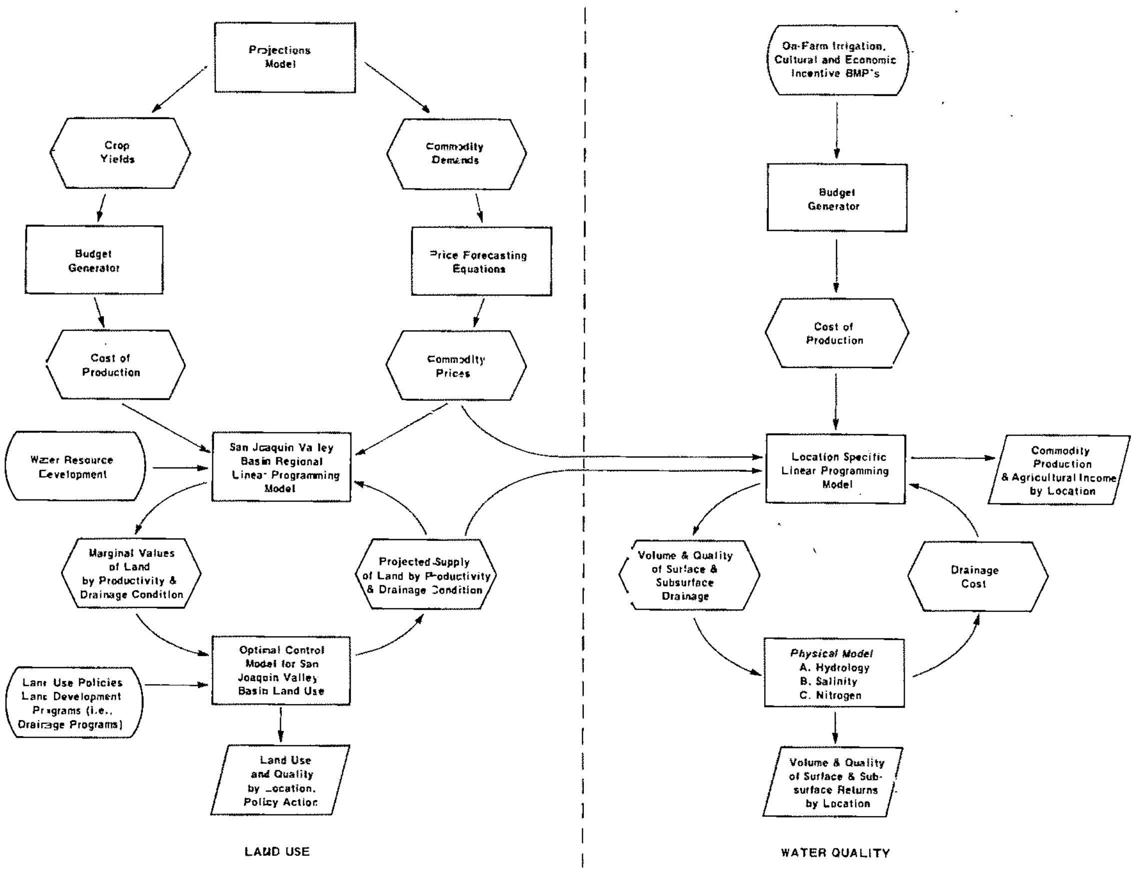

Figure 1. Integrated land use, water resource and water quality analytical system

use produced under alternative land use and water quality policies. Crop rotations for each individual cell are specified according to actual cropping patterns. Drainage costs are reflected in the objective function as determined by the physical model. Cropping patterns can be changed as a result of price changes or they could be mandated as land use or water quality policies. Land conversions from idle to perennial or nonperennial crops can occur if sufficient water supplies are available.

Crop evapotranspiration (ET) is specified in order to isolate water requirements from water application efficiencies. Research is currently being conducted to determine the effects of reducing ET requirements by stressing plants during noncritical stages of growth. Alternative water application technologies available within the production model include furrow and sprinkler systems that are both scheduled and nonscheduled. Water application efficiency and surface runoff are estimated for each technique to account for the total amount of water diverted for irrigation. The possibility of subsidizing more efficient water application techniques has been considered as a BMP to reduce irrigation return flows. Sources of water include surface diversions and wells pumping primarily from the confined aquifer. Levying a pump tax or increasing surface water prices to reduce water use is possible. Surface runoff or tailwater can either be captured and reused or disposed of in surface watercourses. Effluent charges on surface disposal or the subsidization of tailwater recycle systems could be implemented to reduce return flows. Crop nitrogen requirements and alternative application techniques are included as well. Solutions to the LP model are constrained by water supply, processing capacity, crop rotation requirements, and the amount of irrigable land.

Physical Model

Results from the LP model serve as data inputs to the other location-specific model which

describes the response of the physical environment. This physical model is partitioned into two interdependent submodels that analyze the hydrology and salinity balances of the soil profile on the same spatial and temporal basis as the LP. These submodels estimate the effects of irrigation water and fertilizer use on water table depths and the quantity and quality of irrigation return flows.

The hydrology model generates predictions of the rates of deep percolation through the soil, subsurface drainage, rates of groundwater flow among cells, and the movement of the water table in the unconfined aquifer. The soil type, depth of water table, ground surface elevation, and the depth of the impermeable layer are assumed homogenous throughout each cell. In each cell, the annual rate of deep percolation in time t is computed as a function of water inputs and outputs at the surface. Therefore,

$$(1) \qquad DP_{kt} = g_k(I_{kt}, R_{kt}, ET_{kt}, RO_{kt}),$$

where DP_{kt} is deep percolation; I_{kt}, irrigation applications; R_{kt}, rainfall; ET_{kt}, evapotranspiration; and RO_{kt}, surface runoff, all in cell k.

In those cells in which the water table is within 5 feet of the surface, a drainage system is assumed to be installed only if it is determined in the LP model as economically feasible. In a cell where a drainage system has been installed, the rate of drainage is computed from the rate of deep percolation and the movement of the water table. The change in the water table depth between time periods is defined by

$$(2) \qquad H_{kt+1} = H_{kt} + s_k(DP_{kt}, P_{kt}, \sum_{j}^{n} F_{jkt}),$$

where H_{kt} is water table depth in cell k, P_{kt} is water pumped from cell k, and F_{jkt} is groundwater movement from (to) cell j to (from) cell k.

The groundwater flow between cells is calculated according to Darcy's Law, in which spatial and temporal averages of water table depths are used to arrive at an average hydraulic gradient between cells. A spatial average is used as a coefficient of permeability of the cells. The area through which the flow moves is equal to the product of the length of the common boundary and the time-averaged depth of the saturated zones. One equation of the form of equation (2) is written for each cell resulting in n equations for n cells in n unknowns, i.e., the final water table depth for each cell. This system of equations is then solved through Gaussian elimination.

One of the quality changes taking place in the soil moisture is increased total dissolved solids (TDS) concentrations due to evapotranspiration and chemical processes in the soil. Salt pickup in an irrigated soil is primarily a function of the chemical composition of the soil and applied water and the leaching fraction (Rhoades et al.). Analysis of the total annual salt load carried by subsurface drains in the area implied that the total annual salt load per acre in tile drains is related to the total volume of water carried by the drain. It was therefore assumed that the annual rate of salt pickup for each cell can be approximated by the expression,

$$(3) \qquad SL_{kt+1} = SL_{kt} + c_k(DP_{kt}, Q_{kt}),$$

where SL_{kt} is amount of salt in the leaching water, and Q_{kt} is quality of irrigation water applied. These functional relationships were estimated for various qualities of irrigation water using a model developed at the U.S. Salinity Laboratory at Riverside, California (Rhoades et al.).

A weighted average of the salinity concentration of groundwater within a cell is used to estimate the quality of water pumped from drainage sumps and wells within the cell and the quality of water moving outward across the boundaries of the cell. This assumes, in effect, that all strata contribute proportionate shares to flows from the aquifer. Although wells generally will draw water from some strata more than others, it would have been impractical either to differentiate between the various strata in every cell or to determine the characteristics of every well in the study area. In addition, the gravel-pack wells used in the area result in some mixing between strata.

The quality of surface runoff was assumed to be the same as the quality of applied water. This approximation was supported by data observed for various locations in the valley. The salinity submodel estimates the quality of deep percolation as it moves through the unsaturated zone. Water entering subsurface drains was assumed to have the same quality as that of percolation water, at a depth of 6 feet.

Solutions from the models are estimated annually to simulate adjustments derived from policy changes affecting irrigated agricultural practices. Thus, the analytical system is sufficiently comprehensive to evaluate alterna-

tive resource use policies in terms of their economic and environmental impacts. It is structured so as to provide a spatial and temporal dimension for all parameters. Clearly the distribution of resource problems through time and space is a significant determinant of resource policy. In addition, the linkage of micro and macro characterizations of resource use among the component models of the analytical system allows broader implications to be drawn about the nature of demands for land and water resources under diverse sets of policy options. The system is discussed more completely in Horner and Dudek.

Procedure

Cropping patterns, returns to land and management, and the quantity and quality of irrigation return flows in CCID were estimated by the analytical system by subregion for the period 1974–85. Because the integrated analytical system encompasses a substantially greater area than that comprising the CCID, it was necessary to establish a correspondence between subregions and operating units of the irrigation district. CCID is wholly contained within sixteen subregions. The sizes of farm firms in each subregion within CCID were determined from district water billing records. Before tax, farm-related, net returns to land and management for the period of analysis were converted to an average annual present value basis and employed as an estimate of income. These average annual returns were then adjusted to reflect economies of size of operation (Moore, Moore and Hedges). Finally, firms were grouped by income class and Gini ratios were determined for a base situation and two policy alternatives.

Policy Alternatives

The two policies evaluated to reduce irrigation return flows are (*a*) implementing a $22 per acre-foot price for surface water and (*b*) requiring water management practices and methods that result in an increase in on-farm water use efficiency of 30%. Increasing the price of water to account for the negative externalities associated with irrigation return flows is an indirect approach that is necessitated by the nonpoint source nature of the pollution problem. If return flows were a point source problem, an effluent charge would be a direct approach to the internalization of these externalities. Water prices in the West vary because they are established by water agencies and districts to allocate diversion and distribution costs to water users. This pricing structure results in greater water diversions, production, incomes, and return flows than would occur under higher water prices (Howe and Orr, California Department of Water Resources). Increasing the price of irrigation water is as effective as an effluent charge system in reducing environmental damage if diversions are proportional to the pollution caused by return flow disposal. Howe and Orr contend that sufficient correlation exists.

The water management policy assumes continuation of the existing water price structure and imposition of mandatory water conservation practices within the area. Water conservation practices that could be mandated include structural measures for the improvement of water conveyance and delivery systems as well as improved on-farm water management. Distribution system efficiency could be improved through the construction of less permeable canal and lateral linings and the use of flow measurement systems. Improved on-farm water management includes the use of more efficient water application techniques and systems, irrigation scheduling, tailwater recycle systems, decreased furrow slopes and lengths of run, and minimum leaching fractions to decrease deep percolation. It is assumed in this analysis that suitable combinations of these practices, if implemented, would produce an increase in water use efficiency of 30%. Because these practices could be subsidized under the Rural Clean Water Program of the Clean Water Act of 1977, their implementation would result in little or no additional cost to farmers but would represent transfers from the general fund, which should be recognized.

Results

The average returns to land and management per farm firm and the amount and quality of irrigation return flows for the base and two policies are presented in table 1. Average returns decrease slightly as a result of imposing the water management policy. This is because of a slight shift in the location of processing tomatoes outside district boundaries to other subregions within the subbasin. Total re-

Table 1. Average Returns to Land and Management, Amount and Quality of Irrigation Return Flows by Policy

		Policy	
	Base	Water Management Policy	Increased Surface Water Prices
Average returns to land and management per farm firm	$43,768	$42,522	$28,783
Irrigation return flows (AF)	164,000	151,000	103,000
Salt load (tons)	329,000	58,000	213,000
Salt concentration (PPM)	1,836	356	1,897

gional acreage of tomatoes is constrained by the capacity of local processing facilities. Some areas outside CCID were constrained by water supply. Thus, when the water management policy increased the effective supply of water, tomato acreage was increased in these previously water-short areas. More significantly, average returns were decreased by 34% under the policy of increasing surface water prices.

The environmental degradation potential of irrigation return flows within CCID was reduced under either policy option. In the case of the water management policy, total water use was reduced because of improvement in on-farm water use efficiency. Since surface water supply sources for CCID are the least cost, groundwater pumping in the district is reduced. These pumping reductions combined with the naturally higher quality of surface water result in increases in the average quality of applied irrigation water, decreases in the amount of water lost to deep percolation, and improvement in the quality of tailwater and subsurface drainage.

Using the water-pricing policy, the total volume of irrigation return flows is even more dramatically reduced. However, this 37% reduction in return flows belies the fact that salt concentration is approximately the same as in the base period. Because the concentation of salt in return flows is roughly equivalent in the base and water pricing scenarios, total salt load under higher water prices is reduced in proportion to the reduction in return flow volume. Average return flow quality under the improved water management policy, in contrast, is sufficiently good for recycling in agricultural use or disposal without environmental degradation. This substantial reduction in salt load is a direct result of the higher average quality of applied irrigation water and the reduction in volume of both surface and subsurface return flows under the water management option.

Results of the Distributional Analysis

The impact of the two alternative policies on income distribution will be described according to their overall effects, by income class and by income quartile. Table 2 presents basic income distributions for the base, water management policy, and water-pricing option. These distributional impacts are quantified in terms of income and firm number effects. Since the objective function of the location-specific linear programming model maximizes net returns to land and management, no attempt has been made to estimate the dynamic impact of the policy alternatives upon the prices of these inputs. Clearly, changes in water pricing and/or mandated management practices may change expected future returns to these factors of production and thus the intertemporal wealth position of farm firms.

Increasing water use efficiency, when compared against the base condition, has the overall impact of increasing the percentage of income concentrated in the lower end of the distribution of income classes and decreasing that in the upper portion. The largest changes in distribution by income class were a 4% loss in total income share in the $50,001–$60,000 range and a 5% gain by the $70,001–$80,000 class when compared against the base distribution (table 2).[1] Other changes were of a smaller order of magnitude and distributed throughout the range of classes.

[1] These percentage impacts are calculated from table 2 by first determining the percentage of income or firms within an income range in the base period and then subtracting the corresponding percentage outcome from the policy alternative under consideration.

Table 2. Income Distribution under Alternative Water Quality Policies

	Base			Water Management Policy			Increased Surface Water Price

Over 200,000	19	100	100	17	100	100	14	100	100
Gini Coefficient		0.61			0.59			0.65	

In examining the impact upon firm numbers as distributed by income class, it can be seen that the general trend is an evening out with numbers shifting toward the middle from each end of the distribution. The greatest specific changes in firm numbers were 3% losses and gains in the $0–$10,000 and $10,001–$20,000 classes, respectively. The lowest income firms have benefited from the management policy. In addition, there was a 3% decrease in firm numbers in the $50,001–$60,000 classification. The Gini coefficient under the water management option relative to the no-policy option declined from 0.61 to 0.59. Thus, according to this measure, income distribution was improved.

The distributions of income and firms by income class under the water management policy option can also be summarized by aggregating the eleven ranges of income into quartiles. Each of the quartiles would then correspond to the following income spreads: I, $0–$30,000; II, $30,001–$60,000; III, $60,001–$100,000. and IV, greater than $100,000. The changes in income and firm number distributions resulting from the implementation of a policy to improve irrigation efficiency are summarized in table 3. The third quartile, ($60,001–$100,000), is most changed by imposition of the management policy. Firms in the upper end of the second quartile have benefited enough from the reduction in their total water bill through improved irrigation efficiency that they moved into the third quartile. Due to cropping pattern changes in the solution to the programming model with the management policy imposed, firms in the fourth quartile experience income decreases and 1% of them move down into the third quartile.

The overall impact of pricing water at $22 per acre-foot on the relative frequency of income by class is an almost exact displacement of the distribution one class downward relative to the base condition. Firm numbers in all but three classes have been reduced and the greatest concentration of firms occurs in the two lowest income classes. Using this policy, the Gini coefficient has increased to 0.65, thus the income distribution is worsened compared to the base. The specific impacts by class are much greater than those which result under the management policy. Income in the $10,001–$20,000 range increased by 18%, since firm numbers for this class also rose by 18% (table 2). Also heavily affected was the $20,001–$30,000 class, which lost 16% of income and 22% of the firms. Firm numbers in the $0–$10,000 class rose by 12%, bearing out the conclusion that the heaviest impacts accrued at the lower end of the income distribu-

Table 3. Net Changes in Relative Frequency by Quartile as a Result of the Water Management Policy

Quartile	Income Change	Firm Number Change
I	+0.01	0.00
II	−0.03	−0.01
III	+0.04	+0.02
IV	−0.02	−0.01

tion. The increased public revenues generated by this water-pricing policy are presumed to be returned to the general treasury. To the extent, then, that firms in different income classes share differently in the benefits of public programs, the income distributional impacts that have been estimated would be altered.

Examining the impacts by quartile of the water-pricing policy further emphasizes this result (table 4). The only quartile to display relative improvement under this policy option is II, but this is the result of firms in the lower end of the third quartile having income reductions of sufficient magnitude to displace them into the upper end of the second quartile. As has been indicated previously, the heaviest impact on firm numbers is in the first quartile.

In comparing the impacts of the alternative policies to control irrigation return flows, it is important to examine the cumulative distributions presented in table 2. In the base condition, 79% of the firms had 33% of the income, with an average per firm income of $18,275. Under the water management option, 80% of the firms occupied the range $0–$50,000 and had 35% of the income, which averaged $18,603 per firm. However, under the water-pricing policy, 79% of the firms were concentrated in the $0–$30,000 income range, and they shared only 30% of total income. The average per firm income under this policy declined to $10,925.

Conclusions

As a final comparison of the relative impacts of the policies, it is useful to consider the more detailed description of quartile data presented in table 5. It shows firm numbers, the average percentage of total income share per firm, and the average per firm income by quartile and policy. While the average percentage of income share per firm in the first quartile shows little change with either policy, the number of firms and average per firm income do change drastically under the water-pricing option. Firm numbers rise and average per firm income drops. Quartiles II and III are again quite similar for the base and management alternatives. However, water pricing produces a higher average percentage of income share per firm. This is the result of the displacement effect discussed earlier in this section, i.e., firms shifting down into the next lower income quartile. In the highest income quartile, average per firm income drops across policies, with the lowest level occuring under water pricing. In conclusion, then, the policy of water management to improve water use efficiency in order to control irrigation return flows beneficially affects the income distribution among firms in the study area and would thus be favored under the equity criteria employed in this paper.

The objective of this study focused on assessing the distributional impact of two alternative return flow policies on irrigators, representing one sector of the economy. This study does not address the larger question of economy-wide efficiency and equity, which may differ between the two policies. The pricing policy implies the flow of revenue from

irrigators to the general fund and other sectors of the economy. Such revenues could even be used to provide lump sum payments to irrigators. The water management policy through a subsidy program implies a transfer of funds to the irrigators from the general fund and other sectors.

The research presented in this paper is intended to be illustrative of the type of information necessary for the design and evaluation of policies and programs for the control of nonpoint sources of pollution. The approval of Section 208 plans and their related BMPs will depend upon several evaluation criteria. The degree to which an environmental strategy can improve the overall quality of resources is the ultimate criteria. However, Bower et al. characterize the distribution of benefits and costs as the most important physical and economic effect of pollution control. This paper has demonstrated how irrigated farm firms in the Central California Irrigation District would either benefit or bear the costs of return flow control under alternative policies.

Our findings also demonstrate the flexibility of the model in analyzing two quite diverse policy alternatives: improved water use management and increased water prices. This analysis has included the ability to incorporate complex environmental effects, as well. Although the policies selected as illustrative alternatives are obviously not the only choices, their analysis demonstrates that environmental, efficiency, and equity considerations can be comprehensively evaluated in a systematic framework.

Evaluating the Food and Agriculture Act of 1977 with Firm Quadratic Risk Programming

Wesley N. Musser and Kostas G. Stamoulis

Federal agricultural commodity programs generally have been assumed to reduce the income risk for farm firms, but limited empirical research exists on this proposition. This paper presents a study of the impact of the Food and Agriculture Act of 1977 on income risk for a representative farm in Georgia. The model is used to derive an E-V frontier for a firm not participating in the program and for the same firm that is participating in the program. Results indicate that participation dominates nonparticipation except for higher level of expected net income.

Key words: farm management, government commodity programs, quadratic programming, risk.

Farm income stability historically has been a justification for commercial agricultural policy in the United States (Schultz). Under earlier program forms of price supports above market equilibrium levels and maintenance of large Commodity Credit Corporation stocks, the risk arising from income instability was mitigated in conjunction with increasing farm income (Hathaway). With the advent of program forms that separated income support from price supports, reemergence of the income stability problem became a possibility. The increasing importance of agricultural exports, and especially their fluctuations, caused this stability problem to become a reality in the 1970s (Robinson, Schuh). During this same period, a new public commodity program form also evolved for wheat, feed grains, and cotton. The most recent general legislation related to this program form is the Food and Agriculture Act of 1977.

The effectiveness of the current farm program, authorized under the Food and Agriculture Act of 1977, in reducing income instability at the farm level has been given limited empirical consideration. Recent exceptions include Kramer and Pope, who concluded that participation is optimal for risk-averse California producers, and Persaud and Mapp, who found that selected program features can reduce risk in an Oklahoma farm situation. Scott and Baker reached similar conclusions in their earlier study of risk-returns trade-off in an Illinois farm situation, which included government programs under a previous act. The limited empirical analysis is particularly serious since policy analysts disagree on the impact of the Act on risk at the farm level. In the recent U.S. Department of Agriculture (USDA) report on structural issues, Penn, Harrington, and Johnson et al. all asserted (or assumed) that commodity programs reduce risk of farmers. In an earlier policy analysis of the 1977 Act, Spitze concluded that the 1977 Act would contribute to stability of farm income. However, Gardner questioned the effectiveness of the Act in reducing income variability because of its market orientation.

The purpose of this paper is to present an empirical study of incentives for a representative farm firm in South Central Georgia to participate in the 1977 Act. A standard quadratic programming model of a farm firm is used for an expected income-variance (E-V)

Wesley N. Musser and Kostas G. Stamoulis are an associate professor and a former graduate research assistant, respectively. Department of Agricultural Economics, University of Georgia. This paper was written when the senior author was a visting professor in the Department of Agricultural and Applied Economics, University of Minnesota, and the junior author, a graduate research assistant, Department of Agricultural and Resource Economics, University of California, Berkeley.

Vernon Eidman, John Groenewegen, Don Groover, Richard Just, Robert King, Mary Ryan, Fred C. White, and two anonymous reviewers made helpful comments on earlier crafts of this paper.

analysis of the nonparticipation situation. This basic model is then modified to include important policy provisions of the Act, including loan rate, deficiency payments, set-aside, voluntary diversion, and disaster payments, for an E-V analysis of the participation situation. A major methodological problem in the participation model is the estimation of a variance-covariance matrix of incomes for commodities covered under the Act; the approach to this problem used here is to synthesize data to estimate these parameters. The results of the study provide some implications for the risk reduction possibilities of participation in a voluntary commodity program.

Methodological Background

The standard presumption that an important goal of agricultural commodity programs is increased stability of farm income implies the assumption that farmers are risk-averse. The theoretical foundation of this proposition is that farmers maximize expected utility. Assuming that the utility function is quadratic or that net incomes are normally distributed, the optimum under an expected utility objective can be expressed as a trade-off between risks and returns in a quadratic program (Markowitz, Freund). Both sufficient conditions for a mean-variance approach have been considered restrictive (Pratt, Arrow). However, Levy and Markowitz recently demonstrated that the mean-variance approach closely approximates a wide range of situations in which these assumptions do not hold and thereby provides renewed justification for its use. The formulation has been increasingly used in firm risk research in agricultural economics (Anderson, Dillon, Hardaker; Robison and Brake). The form of this quadratic program is as follows:

$$\text{(1)} \qquad \text{Maximize } \mathbf{c}'\mathbf{x} - \frac{\alpha}{2}\mathbf{x}'V\mathbf{x},$$

subject to

$$\text{(2)} \qquad A\mathbf{x} \leq \mathbf{b} \quad \text{and}$$

$$\text{(3)} \qquad \mathbf{x} \geq 0,$$

where **x** is a vector of farm activity levels, c is a vector of expected net revenues from **x**, V is a variance-covariance matrix of net revenues from **x**, α is a scaler risk-aversion coefficient, A is a matrix of input-output coefficients, b is a vector of resource constraints, and ′ is the vector transpose operator. One problem in implementing this model is the choice of an appropriate level(s) of α for microapplications. To avoid the questionable methodology for estimation of α (Young 1979, Grether and Plott), this study derived E-V frontiers which are defined as the change of basis solutions when α is parameterized (Sharpe). These frontiers subsume a large number of risk preference situations and therefore provide a more general analysis of the impact of farm programs on resource allocation.

The methodological approach of other E-V studies which include voluntary government programs has been to include both a participating and a nonparticipating activity in the model for each commodity under the government program (Scott and Baker; Persaud and Mapp). However, this procedure can yield solutions which are inconsistent with the cross-compliance provisions of the 1977 Act that requires participation for all commodities. To incorporate this policy limitation in the analysis, this study derived E-V solutions under two situations: (*a*) participation in the 1977 Act for all commodities and (*b*) nonparticipation in the 1977 Act for all commodities. Considerations of incentives for participation were then based on comparisons of the two E-V frontiers.

Empirical Model

The basic model for this study reflected a representative farm firm in South Central Georgia and was adapted from an earlier linear programming study (Johnson, Saunders, Martin).[1] The firm owned 500 acres of land; however, only the 182.6 acres of cropland were incorporated in the model. The firm had a 60.9-acre peanut allotment and a 21.0-acre tobacco allotment. Crop activities include corn, cotton, peanuts, tobacco, soybeans, second-crop soybeans, wheat, oats, and grain sorghum. Cotton and peanuts were both subject to agronomic restrictions. The farm firm was endowed with 2,500 hours of operator labor, and activities were included to allow hiring seasonal labor in five periods subject to a managerial restraint. The budgets for the

[1] More information on the assumptions and sources of data, the synthesized time series in the participating situation, and the structure of the model are available in Stamoulis and Musser and Stamoulis.

crops reflected above-average management and 1978 prices. The constraints, constraint matrix, and objective function for the nonparticipating farm reflected standard methodology in farm organization studies, except the production and marketing functions of the firm were combined into a single activity for each crop. The variance-covariance matrix was estimated with detrended historical data on gross revenues for crop enterprises for 1958–77 (Georgia Crop Reporting Service).[2]

In the participation situation, the basic model was altered to reflect the voluntary commodity programs. The gross revenue for commodities under this Act were estimated as

$$(4)\qquad R_{it} = P_{it}Y_{it} + A_t DP_{it}Y'_{it} + D_{it}Y''_{it},$$

where R_{it} is gross revenue from crop i in year t; P_{it}, higher of market price or loan rate for crop i in year t; Y_{it}, actual yield of crop i in year t; A_t, the allocation factor for year t; DP_{it}, deficiency payment for crop i in year t; Y'_{it}, normal crop yield for crop i in year t; D_{it}, per unit disaster payment rate for crop i in year t; and Y''_{it}, yield eligible for disaster payment in year t. All definitions are on a per acre basis. DP_{it} is defined as

$$(5)\qquad \begin{aligned} DP_{it} &= P'_{it} - P_{it} \quad \text{if } P'_{it} - P_{it} > 0,\\ &= 0 \quad\quad\quad\quad\;\, \text{if } P'_{it} - P_{it} \leq 0, \end{aligned}$$

where P'_{it} is the target price for crop i in year t. Y''_{it} is defined as

(6)

$$\begin{aligned} Y''_{it} &= d_{it}Y'_{it} - Y_{it} \quad \text{if } d_{it}Y'_{it} - Y_{it} > 0,\\ &= 0 \quad\quad\quad\quad\quad\; \text{if } d_{it}Y'_{it} - Y_{it} \leq 0, \end{aligned}$$

where d_{it} is portion of Y'_{it} covered by disaster payments.

This definition does not include all potential program benefits available under the 1977 Act; data limitations precluded inclusion of disaster payments for prevented plantings, and consideration of the potential benefits for participation in the farm reserve programs were beyond the scope of this study. Thus, equation (4) is a minimal estimate of gross revenue under the 1977 Act.

The model for the participating situation reflected the 1978 program. The only differences in net revenue, or the linear portion of the objective function, for participating firms in this year were deficiency payments for grain sorghum and wheat equal to \$20.35 and \$12.25 per acre, respectively. Voluntary diversion activities were included for cotton, corn, and grain sorghum, which were constrained to be 10% of the planted acreage of the respective crop. A normal crop acreage restriction of 124.96 acres was included, which represented the average land area devoted to the crops covered by the provision in South Central Georgia. All of the crop activities except peanuts and tobacco, which were not included in the normal crop acreage, and the diversion activities had an entry in this restriction. The set-aside provision was incorporated in the model by altering the entries for appropriate activities in the cropland and normal crop acreage restrictions to 1.1 for corn and grain sorghum and 1.2 for wheat; cotton did not have a set-aside in 1978.

A major methodological problem in this study concerned the estimation of the variance-covariance matrix for the participating situation. Historical data on the policy variables included in equation (4) did not exist prior to 1977. Elicitation of a subjective variance-covariance matrix (Anderson, Dillon, Hardaker) also did not appear promising because of the difficulties in eliciting covariances reported by Lin, Dean, and Moore, and more general methodological problems with elicitation procedures (Grether and Plott). As a result, a time series of program variables was synthesized from available information. The basic perspective in this methodology was to determine what would have been the values in equation (4) if the 1977 Act had been in effect in previous years. Scott and Baker appear to have used similar methods in estimation of objective function values for their government program activities. However, their methodology is not explicit in their paper.

Specifications of A_t, d_{it}, and Y'_{it} were straightforward; A_t can vary from .8 to 1.0 with the minimum level set annually by the Secretary of Agriculture. A farm can have the maximum amount if acreages are reduced (or not increased in some years) from that of the previous year. Due to the unavailability of

---

[2] The variate difference method was used to detrend the data. This method allows the mathematically predictable expected components of the data to be removed and the variances and covariances calculated on the residual random component of the data (Tintner, Carter and Dean). The view that all predictable

levels of .6 for wheat and feed grains and .75 for cotton were assumed for d_{it}. Under the Act, Y'_{it} is specified for individual farms as moving averages of previous yields. In this study, Y'_{it} was calculated using historical data on county average yields in these statutory formulas.

The time series for loan rate, target price, and disaster payment rate were based on the assumption that the provisions of the 1977 Act which mandated that target prices be escalated to reflect increases in variable and fixed costs (excluding land) reflected the current political judgment about relationships between payment levels and costs of production. A time series on cost of production is not available so that the Index of Prices Paid by Farmers for Production Items (USDA) was used as a proxy. The 1978 target price, loan rate, and disaster payment rates were multiplied by the ratio of this index in earlier years to the same index for 1978 to calculate these payment levels for earlier years.[3] Earlier studies that have demonstrated political stability in program benefits for specific commodities support this methodology (Field; Rausser and Freebairn).

The gross revenues for corn, cotton, wheat, and grain sorghum under the 1977 Act were calculated with equation (4) using historical data and the synthesized policy variables. Oats and soybeans were eligible for loans under the 1977 Act, but these estimated loan rates were never higher than market prices so the gross revenue time series was the same as in the nonparticipating situation. The loan rate was used for P_{it} only for cotton in 1966, 1969, and 1970; this result was not surprising since the loan rate is designed to be below market levels. Deficiency payments were included for wheat for the period 1968–72, for cotton in 1966 and 1970–2, and for grain sorghum in 1971–2. Disaster payments were paid for wheat in 1972 and 1974, corn in 1969 and 1977, and cotton in 1968–70. Examination of equation (4) demonstrates that gross revenue per acre would never be less than the nonparticipating situation in the participating situation. The preceding summary of program benefits indicates that gross revenue per acre would have been higher in six years for cotton, six years for wheat, two years for corn, and two years for grain sorghum.

The synthesized time series along with the historical time series for oats, soybeans, peanuts, and tobacco were detrended with the variate difference method and the variance-covariance matrix calculated for the participating situation. The variance-covariance matrix for crop activities used in both situations is presented in table 1. The increases in gross revenues for program crops had the expected effects on variances. The reductions in variance for wheat and grain sorghum are slight; however, the reductions for corn and cotton are quite large. Examination of the variance-covariance matrix also reveals another risk-reducing feature of the government program in this analysis—some of the covariances have dramatic reductions. For example, the covariance between peanuts and cotton is -232 and between peanuts and the program cotton is -653; the covariance between corn and soybeans is 300 and between program corn and soybeans is 56.[4] The shift in covariances suggests that government programs can result in risk reduction associated with diversification in addition to direct reduction in variances.

Model Solutions

Optimal parametric solutions for the nonparticipating and participating situations are presented in tables 2 and 3.[5] The E-V frontiers from these solutions appear in figure 1. The most important result in these solutions is that the participation situation dominates the nonparticipating situation at all expected income levels. While this result can be deduced from tables 2 and 3, it is most apparent in figure 1: the E-V frontier for the participating situation is below the frontier for the nonparticipating

[3] Subsequent to the completion of this empirical research, Miller and Sharples considered methods to index commodity program benefits. One alternative used an index of prices paid adjusted for yield changes. In retrospect, adjustment for productivity changes as reflected in yield increases should have been included in this analysis. However, its exclusion resulted in an upward bias in the program payment rates under the assumption that yields have trended upwards over time. The higher program rates resulted in lower estimates of historical program gross revenues than if yields had been adjusted, which is consistent with the general underestimation of program gross revenues in this analysis.

[4] These reductions in covariances are not solely a result of different scales for the data. The correlation coefficient for gross incomes from cotton and peanuts is reduced from $-.12$ to $-.56$ with program participation and for corn and soybeans from .95 to .39.

[5] Some of the solutions with low risk-aversion coefficients do not fully utilize the available land resources. This outcome is not unusual in E-V analyses and these solutions are sometimes deleted as unrealistic (Persaud and Mapp). However, the large amount of idle cropland and cropland used for pasture and forestry in Georgia (White et al.) suggests that these solutions were relevant.

Table 1. Variance-Covariance Matrix for Gross Incomes per Acre of Crop, 1958–1977

situation for all levels of expected returns and widens as the maximum profit solution is approached. These E-V results are consistent with impact of the program on the variance-covariance matrix discussed above.

A modified government participation formulation was constructed to provide an evaluation of the relative importance of the shifts in covariances to the shifts in variance. This formulation was exactly the same as for the participation situation, except that the nonparticipation covariances were included in the model. Solution results for this modified participation formulation are included in figure 1. At low levels of expected income, the variance of net revenue was about the same as the nonparticipating situation, which indicates that the shift in covariances accounted for most of the overall risk reduction at these expected income levels. Above expected income levels of $40,000, the variance of the modified participation solution diverges from the nonparticipation solution; however, the standard deviation of returns at maximum expected net income is $5,631, which is more than $300 above that of the participation situation. Thus, the impact of government programs on covariances of incomes can be quite important for risk reduction. Analyses that consider only

one commodity can significantly understate the risk-reduction benefits of government programs.

With the shifts in variance-covariance matrices between the two situations, reallocation of resources among crops would be expected. Referring to tables 2 and 3, the same activities appear in the solutions with similar patterns.

Solutions with high risk-aversion coefficients include cotton, peanuts, soybeans, and oats. As the risk-aversion coefficient decreases, cotton, peanuts, and soybean levels tend to increase, oats eventually are excluded, and tobacco enters the solution and increases to its maximum level. Differences do exist—soybeans first increase and then decrease and oats reenter the solution when the tobacco allotment constraint first becomes effective in the nonparticipating situation. Another important difference is the level of cotton acreage in the lower part of the participating E-V frontier. For example, the cotton activity was in the solution at 25 acres at expected incomes of about $34,500, and at 61 acres at expected incomes of about $59,500 in the participation situation, while the levels at these expected income levels were 3 acres and 17 acres, respectively, in the nonparticipating situations. Smaller levels of tobacco, soybeans, and oats provided the increased land for cotton in the participating solution. This increased cotton acreage reflects the reduction in risk associated with the government program for this commodity, as no program payments were made for cotton in 1978.

The increased acreage of cotton in the solution and the large reduction in variance of its returns support the view of Gardner and Spitze that the 1977 Act was relatively more favorable for cotton than for other commodities. Two aspects of the solutions indicate that the benefits of the wheat and feed grains program were not so great as for cotton, at least for south central Georgia. First, the benefits of the program were not sufficient to stimulate inclusion of these commodities in the solutions of the participating situations. In addition, program participation reduced the variance of gross returns for wheat and feed grains, but their covariance of returns with other activities in the solution decreased relatively less for these commodities than for cotton (table 1).

The voluntary cotton diversion activity was in all the solutions except the final, profit-maximizing solution. Furthermore, the activity was in all the solutions at their upper level—10% of the cotton activity. Its inclusion in all of these solutions undoubtedly is related to its nonstochastic nature since it was not in the profit-maximizing solution. The shift in the 6.09 acres from voluntary diversion to soybeans in the final solution increased profits about $64 per acre and standard deviation of profits about $400. It also can be noted that the expected returns from the wheat and feed grain voluntary diversion programs were not sufficient to draw these crop activities into the solution.

The existence of no set-aside for cotton in 1978 decreases the generality of the results in tables 1 and 2 because of the importance of the cotton activity in these solutions. With a set-aside in effect for cotton, the program solutions would have less total crop acreage if cotton were included. To explore this possibility, a solution was obtained for a participating situation in which a 10% set-aside was required for cotton. This solution again included the same activities. However, the levels of some activities were lower in most solutions because of the cotton set-aside. The maximum profit solution had a net income of $82,016 and a standard deviation of $5,286 (Stamoulis). As expected, the idle land required for the set-aside resulted in lower net income than in the nonparticipating situation—the final three solutions in the non-participating situation had higher net income than $82,016 (table 2). Achievement of these higher expected profits required a corresponding increase in risk—the standard deviation of returns at maximum profits in the nonparticipating situation was $6,500 (table 2). Unless farmers are risk-neutral or risk seekers, they would be expected to participate in the government program in this representative situation.

Conclusions

This study has provided empirical support for the widely held view that government agricultural commodity programs reduce the risk faced by agricultural producers. In an E-V framework, program participation resulted in lower variance of net income for all levels of net income achievable both with and without program participation for a representative farm situation in south central Georgia in 1978. When a set-aside was required for cotton, slightly higher net income was achievable without participation. The importance of the risk reduction aspects of the program was particularly important in these results because the expected returns of the activities in the solution were the same in both situations. These results imply that farmers represented by this model who have any degree of risk

aversion would have had incentives to participate in the 1978 program.

Available data on program participation in this area in 1979 do not necessarily support this strong conclusion. Using program compliance data for 1978 (Georgia State ASCS Office) and number of farms with crops production in 1974 (U.S. Department of Commerce), 49.4% of the farms participated in the program. The range among counties in the area was 21.9% to 78.3%. The lower level of participation than predicted from the model undoubtedly reflects the high level of cotton production and zero corn production in the solutions. As in the earlier study with this constraint matrix (Johnson, Saunders, Martin), these results are inconsistent with actual production patterns in this area, which included large corn acreage and very small cotton acreage. This divergence from representative data is not uncommon in mathematical programming models and reflects several considerations in this study. Most important, many farmers do not have the management skills required to achieve the level of cotton production reflected in this model or are unwilling to make the specialized investment in a cotton harvester with fluctuating cotton prices. In addition, more stringent rotational constraints and/or land quality constraints would have resulted in a substitution of corn for cotton and soybeans. With more corn in the solutions, the reduction in expected net income because of the corn set-aside would have decreased incentives for participation. Analysis of the impact of a cotton set-aside indicated that the basic results of the analysis if more corn was in the solution would still hold except that higher expected returns would be achievable without participation, so that risk-neutral producers, and probably even those with low positive risk-aversion coefficients, would have incentives not to participate.

While generalization of results from representative farm situations is not usually possible, some implications of the study are likely to hold in other geographical and temporal situations. Most important, the decision to participate in voluntary farm commodity programs involves the familiar risk-returns trade-off—participation will reduce expected net returns and also risk. The trade-off arises because the opportunity cost of the land required for the set-aside is higher than the income benefits of the program, particularly if land resources are homogenous and have high productivity. The normative side of this implication is that participation in voluntary programs with payment levels such as the 1977 Act likely will be optimal for risk-averse producers; producers with higher risk-aversion coefficients, and/or more business and financial risks will more likely participate. These implications are consistent with the microstudies in other geographical areas (Scott and Baker, Kramer and Pope, Persaud and Mapp).

The study also suggests some implications for interaction between commodity program features and likely participation in certain situations. Most obviously, the level of set-aside will affect participation. With a zero set-aside, the risk reduction aspects of the program are available with zero opportunity costs. A related implication is that level of opportunity costs of the set-aside is likely to be inversely related to participation. In areas with higher quality land than in Georgia, the divergence between maximum expected incomes caused by the set-aside likely will be higher. An additional implication is that the risk-reduction benefits of the wheat and feed grain programs are generally less than for cotton, so that the incentives for participation likely would be less for situations in which these crops are more important. However, this proposition may not hold for situations in areas where wheat and feed grains are subject to more income risk than in south Georgia. Finally, the normal crop acreage restriction likely would be more limiting in situations with adjustable acreages of crops not included in the restriction; the government program would involve larger risk-returns trade-offs in situations in which land was being transferred from hay, pasture, or horticultural crops to field crops.

The policy implications of this research are further supported by the overall tendency of the methodology to underestimate the times series of gross income from program participation. Payments for prevented plantings and benefits of the farmer reserve program were not considered in the analysis. Assuming the minimum value of the allocation factor also reduced the level of deficiency payments. In addition, market prices in the period from 1958–65 reflected higher price supports than under the 1977 Act, which resulted in no government program benefits during this period in the participating time series. A time series of participating gross revenues that did not in-

clude these underestimation features undoubtedly would have small variances and even more risk reduction than indicated in this analysis.

The analysis in this paper also has some methodological implications. Most important, analysis of the impact of variation in program benefits and requirements on the incentives to participate in government programs needs to be in an expected utility framework. This implication arises from the view that farm income stability has always been an important goal of farm policy, and the results of this study support the view that currently it is the most important benefit for farmers. Risk-return analysis of farm commodity programs also must allow evaluation of the resource reallocation in response to the portfolio effects of the program. In this paper, the shift in covariances between crop incomes was as important as the direct reduction in variance of income from cotton. However, more research in other areas is necessary to determine the generality of this effect on covariances. A broader methodological implication is that synthesizing a time series to estimate variance-covariance matrices is a potentially useful alternative to subjective elicitation when historical data are available and bears attention in future research.

Further empirical research on the issue of risk reduction from government commodity programs is warranted. More research for other microsituations would be helpful in validating the implications of this paper. In addition, such research should consider incorporating the aspects of commodity program excluded from this analysis. For example, an expanded model could include marketing activities to allow consideration of the farmer reserve program. Consideration of alternative policy deflation (inflation) methods would be directly helpful in designing farm commodity legislation. Finally, methodologies other than risk programming may be appropriate to accommodate some of the limitations of this methodology (Robison and Brake).

Forecasting Short-Run Fed Beef Supplies with Estimated Data

James N. Trapp

Unknown aggregate data series for the placement weight, growth rate, and sex composition of cattle placed on feed are estimated. The estimates are made by treating the unknown data as time-varying parameters of a cattle-on-feed growth and inventory stimulation model. A nonlinear optimization algorithm is used to estimate the unknown parameter series that optimize the model's simulation accuracy. Incorporation of the estimated series into a traditional econometric fed-beef-supply forecast model improved the model's forecast accuracy. The methodology used provides a general procedure for estimating unknown aggregate data using simulation models based upon microrelationships.

Key words: beef supply, forecasting, nonlinear optimization, parameter estimation, simulation.

Agricultural economics research often is hampered by a lack of appropriate data. In such cases researchers have either ignored the relations described by the missing data or attempted to develop a proxy for them, hoping that some consideration of these relations is better than ignoring them. Keith and Purcell point out that voids exist in U.S. Department of Agriculture (USDA) cattle slaughter data, making it impossible to trace cattle inventories from birth to death. This hampers analyses of the cattle cycle and forecasts of beef supplies.

A common traditional model used by outlook economists in making short-run fed-beef supply forecasts illustrates the limitations created by voids in physical data describing cattle on feed. The model regresses fed beef slaughter one to two quarters in advance upon current cattle-on-feed numbers by weight groupings. Such forecasts either ignore or crudely approximate known information about beef growth relationships; i.e., variations in growth rates due to seasonal weather conditions are proxied by dummy variables; changes in growth rates due to improved breeding, feed additives, and other factors are ignored; effects of the animals' placement weights upon their growth rates, eventual slaughter weights, and dates of slaughter also are ignored.

It is the premise of this research that an objective method of estimating aggregate physical data series for cattle on feed, such as placement weights and growth rates of cattle on feed, coupled with knowledge of the beef growth process, can provide information beneficial to short-run fed-beef supply forecasting. Consider a short-run, fed beef-forecasting model of the following form:

$$(1) \qquad \text{fed beef supply} = f(\mathbf{X}, \quad \hat{\mathbf{U}}),$$

where $\mathbf{X}$ is a vector of observable variables and $\hat{\mathbf{U}}$ is a vector of estimated values for unobserved, but relevant, physical data. The methodology developed here estimates the unknown physical data series $\hat{U}$ as a set of time-varying parameters of a growth and inventory simulation model of cattle on feed. As a simplified example, consider

$$(2) \quad Y700_t = g(Y700_{t-1}, \quad Y500_{t-1}, \hat{U}1_t, \hat{U}2_t, T),$$

where $Y700_t$ represents the reported number of 700–899-pound steers on feed at time t; $Y500_{t-1}$, the number of 500–699-pound steers on feed the previous period; and likewise $Y700_{t-1}$, the number of 700–899-pound steers on feed the previous period. $\hat{U}1_t$ and $\hat{U}2_t$ represent specific time-varying parameters of the general vector $\hat{\mathbf{U}}$ above. In this case $\hat{U}1_t$ represents the number of 700–899-pound steers

James N. Trapp is an associate professor in the Department of Agricultural Economics, Oklahoma State University.
Oklahoma Agricultural Experimental Station Journal Article No. 3621.

placed on feed during period t, and $\hat{U}2_t$ the daily growth rate of steers, while T is the number of days between t and $t-1$.

Within the model structure, given $Y700_{t-1}$ and $Y500_{t-1}$, alternative values for $\hat{U}1_t$ and $\hat{U}2_t$ can be used to simulate the number of steers entering and exiting the $Y700_t$-weight group of cattle and hence its inventory state at time t. Based upon this structure, $\hat{U}1_t$ and $\hat{U}2_t$ can be estimated with the objective of accurately simulating $Y700_t$. The unknown physical data series to be estimated in this study include (*a*) the average growth rate of cattle on feed, (*b*) the placement weight of cattle on feed, and (*c*) the sex of cattle placed on feed.

The growth and inventory simulation model for which the unknown physical data series were estimated is based upon an individual animal growth model. However, because the data series desired are aggregate in nature, the individual animal growth model was not used directly, but its basic concepts were used to develop an aggregate model. The physical data series estimated have been incorporated into an econometric fed-beef-forecasting model with beneficial results. This general methodology may be of use elsewhere when lack of data hampers research.

Growth and Inventory Model for Cattle on Feed

The basic structure of the growth and inventory model for cattle on feed is shown in figures 1 and 2. As depicted in figure 1, the model contains seventeen inventory categories, three placement weight alternatives for steers, and three for heifers. A uniform distribution of placement weights for cattle in each weight category is assumed, while the distribution among categories is left to be estimated.[1]

Each placement weight alternative results in a unique growth path and slaughter weight. Figure 2 depicts a typical set of growth paths and slaughter weights for steers placed at dif-

[1] It is assumed that no steers weighing less than 350 nor more than 899 pounds and no heifers weighing less than 300 nor more than 899 pounds are placed on feed.

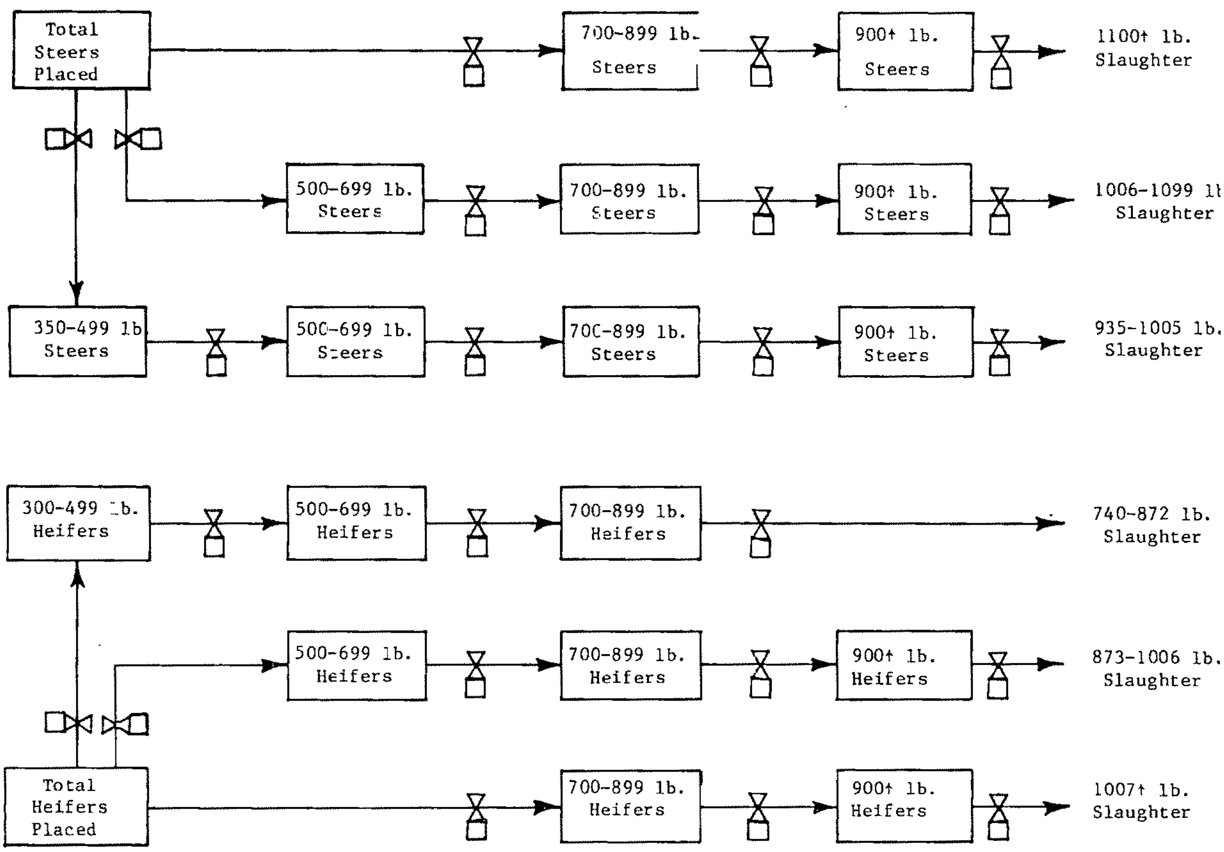

Figure 1. Growth and inventory model for cattle on feed

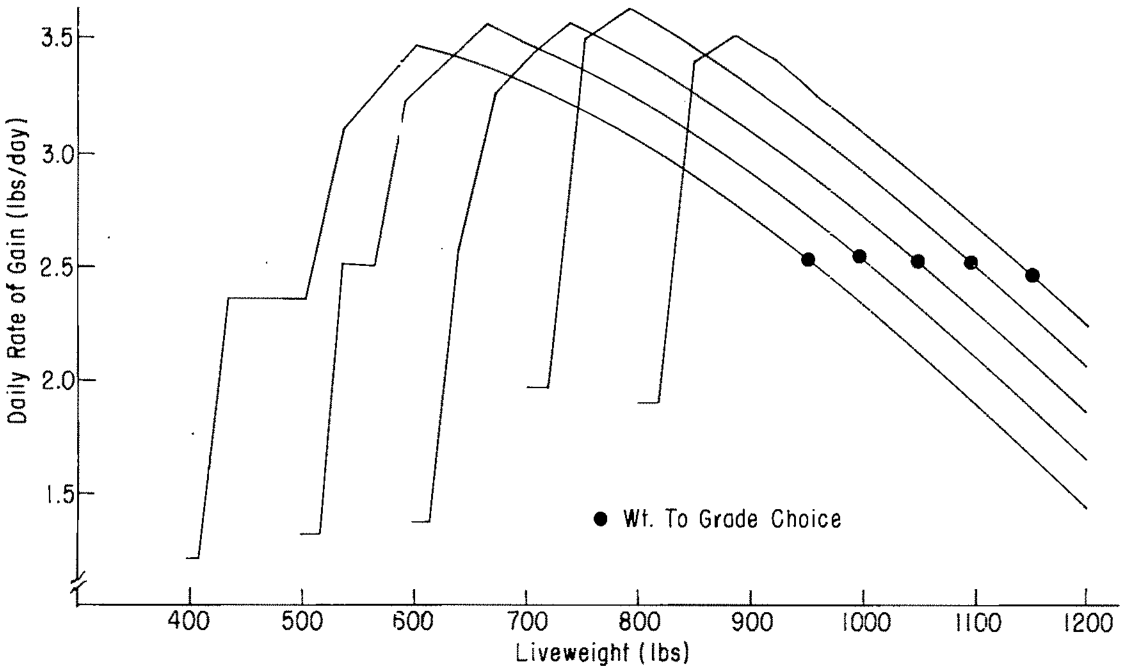

Figure 2. Typical daily rates of gain for steers by placement weight and current weight

ferent weights.[2] A similar set of curves can be developed for heifers. Figure 2 is derived from a biological growth model of a beef animal developed by Nelson. His work draws heavily upon that of Gill and Lofgreen and Garrett and is similar to that of Fox and Black.

The growth patterns and inventory categories depicted in figures 1 and 2 are incorporated into a computerized growth and inventory simulation model for cattle on feed. A modified version of a continuous distributed delay subroutine developed by Pugh is used to simulate the growth and inventory process for each of the seventeen inventory groups. This subroutine is capable of simulating the daily flow of cattle into and out of each given inventory category and of maintaining an inventory count for each category. Parameters required to accomplish this include the average daily growth rate of animals in the category, the weight range of the category, and the daily number and weight of animals entering the category. The growth and inventory model for cattle on feed is a collection of seventeen such subroutines linked together; i.e., the simulated outflow of the delay model describing the 350–499-pound steer inventory category is the input to the delay model for the 500-699-pound steer inventory category in the lightest steer placement-weight growth path.

The growth curves depicted in figure 2 for steers and a similar set of curves derived for heifers (from Nelson's model) are used to specify the relative growth rate relations among the seventeen inventory groups while the general rate of growth is estimated. Thus, a single-valued shifter of the curves depicted in figure 2 is estimated. It decreases or increases the base set of assumed growth curves, but does not alter the relations between the curves.

Estimation of the Unknown Physical Data Series

The unknown data series to be estimated are time-varying parameters of the distributed delay model. They are the general growth rate of animals on feed, the weight category within which animals are placed, and the sex of animals. The task specified for the estimation procedure is to determine the set of unknown parameters which will result in the most accurate simulation of the reported quarterly data of historical cattle on feed and marketings. The objective function consists of the weighted sum of squared errors in predicting nine inventory levels, the total number of cattle on

[2] The distinct discontinuities observed in the 400- and 500-pound beginning weight curves are due to assumed ration changes which disrupt feeding and growth patterns for brief intervals.

feed, and fed cattle marketed. This function is minimized each quarter to generate one set of time-varying parameter estimates.

$$
\begin{aligned}
(3)\quad OBJ = {} & ESTEER^2(350\text{–}499) \\
& + ESTEER^2\,(500\text{–}699) \\
& + ESTEER^2(700\text{–}899) \\
& + ESTEER^2(900\text{–}1{,}099) \\
& + ESTEER^2(1{,}100 \text{ and above}) \\
& + EHEIF^2(300\text{–}499) \\
& + EHEIF^2(500\text{–}699) \\
& + EHEIF^2(700\text{–}899) \\
& + EHEIF^2(900 \text{ and above}) \\
& + 9 *ECOF^2 + EMARKET^2,
\end{aligned}
$$

where OBJ is the sum of squared-errors objective value to be minimized; $ESTEER^2(I-J)$ is the square of the difference (error) between the reported and estimated numbers of steers on feed in weight category $I-J$, i.e., 499 pounds and below, 500–699 pounds, 700–899 pounds, 900–1,099 pounds, and 1,100 pounds and above; $EHEIF^2(I-J)$ is the square of the difference (error) between the reported and estimated number of heifers on feed in weight category $I-J$, i.e., 499 pounds and below, 500–699 pounds, 700–899 pounds, and 900 pounds and above; $ECOF^2$ is the square of the difference (error) between the reported and estimated numbers of cattle on feed at the end of the quarter; and $EMARKET^2$ is the square of the difference (error) between the reported and estimated numbers of fed cattle marketed during the quarter. The error in estimating total cattle on feed is weighted nine times more than other errors since it is the summation of nine weight categories.

Estimation of the time-varying input parameters is conducted as a nonlinear optimization problem. (For a detailed discussion of this estimation procedure, see Richardson, Ray, Trapp.) The nonlinear optimization algorithm used was developed by Box and is referred to as the "Complex Algorithm." It consists of a heuristic search procedure capable of finding the minimum or maximum value of a nonlinear objective function subject to nonlinear constraints.

To estimate a series of time-varying parameters, values for each quarter are considered in sequence. At the end of each quarter, any errors in estimating the size and weight distribution of the ending inventory of cattle on feed are corrected by using data reported in *Cattle on Feed*. Hence, previous errors will not affect parameter estimates for the following quarter.

The simulation accuracy achieved with the growth and inventory model using the time-varying parameters estimated was quite good over the period 1960–1978. The R^2 for simulating the number of cattle on feed was .99, with an average percentage error of 1.57%. The largest single percentage error was 6.76%. The R^2 for simulating the number of cattle on feed marketed was .98, with an average percentage error of 2.86%. The largest single error was 14.17%.

Estimated Data Obtained

Operation of the model and optimization algorithm over the period 1960–78 yielded time-series estimates of placement weight, sex of animals placed, and average aggregate growth rates. Tables 1 and 2 report average seasonal patterns and annual averages for these data series over the period 1960–78.

Growth rates are estimated to be most rapid in the first and fourth quarter and slowest in the third quarter. Seasonal fluctuation is due both to climatic factors and the type of backgrounding received by cattle placed at different seasons. The steer/heifer ratio (sex ratio) of cattle placed on feed indicates that proportionately fewer heifers are placed on feed in the first and fourth quarters. Last, the estimates of the average weight of cattle on feed (which is not an estimated variable but a descriptive output of the model) indicates that the heaviest average weight of cattle on feed occurs in the second quarter and the lightest in the fourth. The seasonal pattern of the average weight of cattle on feed is correlated with the seasonal pattern for number of animals placed and with the average weight of animals placed.

The placement weight information generated by the model is perhaps the most useful. The estimates indicate that a significant portion of cattle placed weigh less than 500

Table 1. Selected Average Estimated Characteristics of Cattle on Feed and Placed on Feed by Quarter, 1960–1978

Quarter	Growth Rate Index	Sex Ratio of Cattle Placed on Feed Steers/Heifers	Average Weight of Cattle on Feed
1	104	3.20	815
2	100	2.15	834
3	89	1.92	821
4	105	2.24	768

Table 2. Estimated Seasonal Distribution of Average Weight and Numbers of Cattle Placed on Feed, 1960–1978

	Percentage Placed				
Quarter	Under 500 lbs.	500–699 lbs.	700–899 lbs.	Average Placement Weight	Index of No. of Cattle Placed on Feed
1	53.2	40.3	6.6	518	85
2	26.7	66.3	7.6	571	83
3	26.5	43.7	29.8	612	97
4	64.4	26.5	9.1	502	135
Annual avg.	42.2	44.5	13.2	549	100

pounds, i.e., 42.2% (table 2). This is not surprising because the turnover rate of cattle on feed under 500 pounds is the most rapid of any reported weight group. Cattle typically gain only 50–75 pounds while in this weight classification, compared to 200 pounds in others. Hence, to maintain a given inventory of cattle on feed under 500 pounds requires more placements than to maintain the same inventory in other weight classes where the turnover rate is three to four times slower.

The estimates reported in table 2 indicate that the majority of the placements under 500 pounds occur during the first and fourth quarters. The heaviest average placement weights occur in the second and third quarters. The largest percentage of cattle (66%) placed in the second quarter is in the 500–699-pound range. This group likely consists of spring calves that have been wintered, grazed on spring pasture, and sent to feedlots.

The time-series paths of the annual average values found for the estimated variables are presented in figures 3A–3C. The sex ratio (fig. 3A) is correlated with the cattle cycle (fig. 3D) measured as the annual index of the rate of change in the size of the cow herd. The simple correlation coefficient (r) is +.67. The sex ratio appears to rise during periods of expansion because more heifers are held for replacements, thus causing the steer/heifer ratio to rise.

The placement weight series is not strongly correlated with the cattle cycle but does appear to be cyclical. During 1974 and 1975, when feed prices were high relative to cattle prices and "grass fed" beef was common, estimated placement weights were the highest observed for the period, 1960–78.

The index of growth rates, figure 3C, does not seem to follow the cattle cycle. When re-

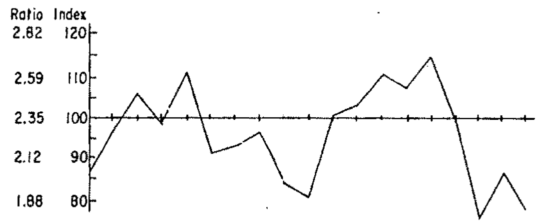

Figure 3A. Steer/heifer sex ratio of cattle placed on feed, 1960–1978

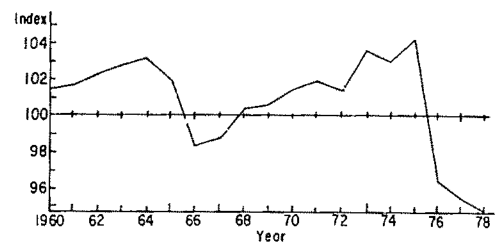

Figure 3D. Rate of change in size of the beef cow herd, 1960–1978

gressed against time, it shows a significant positive trend, primarily due to the unprecedented rise in growth rates since 1973. The drop in growth rates observed from 1970 to 1973 may have been due to the legal actions taken against some growth hormones and feed additives. The rapid estimated increases in the growth rates of cattle on feed since 1973 are sustained by observations of animal scientists. They attribute much of this rise to increased cross-breeding and the development of alternative legal hormones and feed additives.

Application of Estimated Data

Two econometric forecasting models were developed, one that directly incorporates the estimated data and a second based upon proxy variables for the estimated data. The first is a respecification of the "traditional" single-equation, short-run, cattle-on-feed-marketing-forecast model mentioned earlier. This traditional model was respecified to incorporate the data derived in the previous section in the form of three quarterly, seasonally adjusted indices. They are indices of growth rates, slaughter weights, and placement weights. The second forecast model is similar to the first, except that the three indices used in the first model are replaced by proxy variables developed from reported cattle-on-feed data.

Model 1

Three seasonally adjusted, quarterly indices based upon the estimated data are incorporated into Model 1. The indices include a growth rate index constructed by seasonally adjusting the quarterly growth rates for 900-pound steers,[3] an index of slaughter weights formed by calculating a seasonally adjusted, weighted-average index of steer and heifer slaughter weights,[4] and an index of placement weights designed to describe the seasonally adjusted variation in placement weights of steers and heifers on feed and currently weighing over 900 and 700 pounds, respectively.[5]

All three of the indices as used in the model are either lagged or based upon lagged data. Therefore, the data required to calculate the indices and make forecasts are available upon the release of the USDA cattle-on-feed report early in the quarter being forecasted. Lagged, as opposed to current period values of the indices, were used to facilitate forecasting. First-order autocorrelations (R^2) of the indices are approximately .7, making one-period lags of each indice a reasonably good proxy for its current period value.

Ordinary least squares estimates of the "traditional" and new Model 1 over the period 1960–76 are reported in table 3. In general, the statistical properties of Model 1 appear superior to those of the traditional model. The three added variables are each significant at the .025 level or better. The estimated standard error of Model 1 is 24.3% less than that of the traditional model. The traditional model left 10.4% of the variation in fed cattle marketings unexplained compared with 5.7% for Model 1. The presence of the three index variables in Model 1 appears to improve the specification of the model by removing a significant amount of serial correlation.

Each of the coefficients for the lagged indices added to Model 1 displays a plausible sign if they are proxies of the current period value. A positive sign is expected for the coefficient on the growth rate index because faster growth rates would be expected to decrease the remaining time on feed of a group of cattle nearing slaughter weight. Increases in slaughter weight, *ceteris paribus*, would extend the time cattle are on feed and thus reduce the flow of slaughter. Hence a negative sign is expected for the coefficient of the slaughter weight index.

Deducing the plausible sign for the placement-weight index coefficient is more difficult. The physical growth relations of figure 2 indicate that placement weight affects both the slaughter weight and growth rate of steers on feed. The increase in slaughter weights associated with heavier placement

[3] Since growth rates for all sex and weight categories of animals included in the beef simulation model are held in fixed ratios to each other, the specific weight-sex category chosen does not affect the values derived for the index.

[4] The index of slaughter weights was formed by calculating a seasonally adjusted, weighted-average index of steer and heifer slaughter weights. Relative weights for the averaging process were based upon the number of fed steers and heifers estimated by the cattle-on-feed model to have been slaughtered during the quarter.

[5] The index of placement weights was formed by calculating the weighted-average weight of four lagged categories of steer placements and three lagged categories of heifer placements. Lagged placement weight groups included were two-quarter lags for (*a*) 350–499-pound steers, (*b*) 500–699-pound steers, and (*c*) 300–499-pound heifers. One-quarter lags were included for (*a*) 500–699-pound steers, (*b*) 700–899-pound steers, (*c*) 500–699-pound heifers, and (*d*) 700–899-pound heifers.

weights tends to dominate the effect of the increase in growth rates also associated with heavier placement weights. Hence, cattle placed on feed at heavier weights tend to spend more days on feed after they reach 900 pounds than cattle placed at lighter weights. Therefore, it follows that the expected sign for the placement weight index coefficient is negative.

Model 2

The specification of Model 2 was prompted by the success of Model 1. Model 2 uses indices which proxy those of Model 1 but which can be developed from reported, rather than estimated, data. The index of average steer and heifer slaughter weights used in Model 1 is proxied by a seasonally adjusted index of steer slaughter weights. To proxy the placement weight index, a seasonally adjusted index of the ratio of the number of cattle on feed under 500 pounds versus the number over 500 pounds is developed. It is hypothesized that increases in the number of cattle on feed under 500 pounds relative to other weights reflects a decline in placement weights. Last, the index of growth rates is proxied by a seasonally adjusted ratio consisting of the sum of the number of steers on feed over 900 pounds plus the number of heifers over 700 pounds at the beginning of each quarter divided by the number of cattle marketed during the quarter. It is hypothesized that a decrease in this ratio reflects an increase in the growth rate of cattle on feed. The more rapid the growth rate the

more cattle will be marketed during the quarter, relative to the initial number of heavier weight cattle on feed. Lagged values of these three indices are used in Model 2. The estimated model is reported in table 3.

Comparison of Model Forecasts

Ex post forecasts for 1977 and 1978 from the traditional model, Model 1, and Model 2 are presented and compared in table 4, with actual data and estimated marketing intentions determined by the USDA from its quarterly survey of cattle feeders in twenty-three states. Model 1 provides the best set of forecasts and is a distinct improvement over the traditional model. Model 2, which uses only reported data, is also more accurate than the traditional model but not as accurate as Model 1.

The forecasts generated by Model 1 have almost identical accuracy to estimated marketing intentions as reported by the USDA and based upon its quarterly survey of cattle feeders. Note that Model 1 does not use any information from the 1977–1978 period to adjust its parameter estimates. If the parameters of Model 1 are updated over the 1977–1978 period and forecasts made with the updated parameters, the model's root mean squared error, mean absolute error, and Theil inequality coefficient become 164.5, 135.9, and .0127. These values are slightly superior in each case to those of the reported marketings intentions series.

Summary

This study illustrates methodology for estimating physical data series for cattle on feed which are not currently reported by the USDA. Incorporation of the estimated physical data series in an econometric fed-beef supply-forecasting model results in improved accuracy of short-term fed-beef supply forecasts. Each of the estimated data series, when incorporated into the model, generates estimated parameters with expected signs and a high degree of statistical significance. The estimated physical data series obtained also were useful in developing a deeper understanding of seasonal and year-to-year historical changes in growth and slaughter patterns for cattle on feed.

The methodology developed appears to be potentially useful in many areas of agricultural research. Specifically, it appears possible to estimate unreported aggregate-average physical data series from knowledge of microphysical relationships. In this study, microphysical relationships were used to specify the structure of an aggregate cattle-on-feed growth and inventory model. Unknown time-varying physical parameters of this model were then estimated via optimization of the model's simulation accuracy. It is possible to revise and/or expand the growth and inventory model for cattle on feed so that other types of information, in the form of estimated time-varying parameter data series, can be obtained. Such information might include the

Table 4. Comparisons of *Ex Post* Forecasts of Three Cattle on Feed-Marketings Forecast Models with Actual and Reported Marketing Intentions Data

feed consumption of cattle on feed, placements of cattle on grass, aggregate grass-fed-beef growth rates, and seasonal calving patterns of the national cow herd. Attempts to determine what factors explain the variation in the estimated data series appear to hold promise for developing a deeper understanding of fed-beef supply forecasting. With suitable modifications, the methodological approach and the model developed probably can be used in analysis of production and supply of other types of livestock.

Portfolio Theory and the Demand for Futures: The Case of California Cotton

Peter Berck

This paper examines the simultaneous choice of cropping pattern and futures positions. It derives the demand for hedging as a function of the price of a hedge and the crop choice set; it estimates these functions for California cotton farmers. It finds that both the costs of hedging and the opportunity to diversify risk by growing other crops substantially change the optimal hedge for California cotton farmers.

Key words: cotton, finance futures.

Farmers and inventory holders both can use futures markets to reduce risk. However, a survey by the Commodity Futures Trade Commission (CFTC) shows that only 5% of farmers participate directly in futures markets and as many as a third do not know how the markets work. From its survey, the CFTC concluded that it should provide more education to farmers so that more farmers would hedge. The CFTC's conclusion is not justified because the economic interest of farmers may not lie in their use of futures markets. The purpose of this paper is to lay out the factors that influence farmer hedging and to estimate their empirical importance.

The basic framework is a mean-variance portfolio analysis which is the same framework as that used by Peck, Rolfo, or Rutledge. The model differs from that of Peck or Rutledge because they assume hedging is costless, but we settle the hedging cost empirically. The model differs from that of all three previous authors in the simultaneous choice of both crops and futures. This approach consolidates the choice of the crops approach of Freund; Carter and Dean; and Lin, Dean, and Moore, with the choice of futures approach of Peck, Rolfo, and Rutledge. Both allowing for a risk premium and simultaneously choosing crops and futures make large differences in the optimal hedge and in the location of the mean-variance frontier.

The remainder of the paper is in four sections. The theory section sets out the objective function and constraint set. It presents a formal optimization model. In the second section I discuss the estimation of the means and variances of crop futures returns. In the third section, the empirical results include (*a*) a description of the mean-variance frontier, (*b*) the choice of an efficient plan, (*c*) the benefits of diversification, (*d*) the effects of diversification on hedging, (*e*) the effects of changing the price of a hedge, and (*f*) the effects of forecasting. The conclusions are presented in the final section.

Theory

The discussion of the farmers' portfolio problem proceeds by stating the objective function, defining the constraint set, and deriving the Kuhn-Tucker conditions for a maximum. In passing, the discussion makes six important points: (*a*) farmers make simultaneous decisions on crops and futures; (*b*) they evaluate losses differently than gains (skewness); (*c*) futures holdings tie up their credit; (*d*) mortgages leave them leveraged; (*e*) hedging results in an expected loss; and (*f*) forecasting allows a gain on futures.

For computational ease, most authors in finance literature (Tobin, Markowitz, and

The author wishes to thank Oscar Burt, Bruce Dixon, Richard E. Just, Andrew Schmitz, and Paul Samuelson for helpful suggestions and Gordon C. Rausser for his criticism of an earlier draft and insights on the costs of futures-market participation. He would also like to thank Constance Cartwright for able statistical assistance and Patricia Colleran for accurate assembly of this document. Any remaining errors are the author's.

Sharpe) and in futures literature (Peck, Rolfo, and Rutledge) approximate a more general expected utility objective function with a two-period, mean-variance framework. The approximation does not allow for plan revision, restricts the form of the utility function, and ignores skewness. We treat these items in turn. Plan revision—changing the quantity hedged—should occur as the growing season progresses and yields become more certain. Although Samuelson provides a more general control model for such a situation, it was not adopted for computational reasons. Restricting the utility function to generalized mean variance—$U(M, V)$, increasing in mean, M, and decreasing in variance, V—permits close approximation of the other utility functions common in finance (Levy and Markowitz) and permits a two-stage computation procedure. First, the mean-variance frontier—the locus of minimum variance for given mean—is computed. Then, any $U(M, V)$ function can be used to pick a point on the frontier. The major drawback to the use of mean-variance analysis in agriculture is that yields are known to have skewed distributions (Day) which might distort the ability of variance to represent downside risk. A Chebychev inequality on semivariance is used to check on the effect of nonsymmetric distributions on portfolio choice.

The constraints on wealth (or credit) and land define the farmer's choice set. A farmer has fixed acreage L, debt D, and allocatable credit (and wealth) W. The L acres are split among crops with acreage, A_i, or left idle. In a vector notation, let $\mathbf{A}' = (A_1, \ldots, A_n)$ and $\mathbf{a}' = (1, \ldots, 1)$ so

$$(1) \qquad \mathbf{a}'\mathbf{A} \leq L.$$

Allocatable credit, W, is split between futures, F_i, that tie up f_i dollars each or is unused, B. Each futures impinges on the credit constraint by the maximum amount the farmer is prepared to lose on that contract (worst possible variation margin) and the initial margin. Again, utilizing vector notation,

$$(2) \qquad W \geq \mathbf{f}'\mathbf{F} + B.$$

More generally, wealth could have been allocated to financial assets other than the implicit bond, B, which pays off rB in period two, or to futures. Stocks, options, city real estate, or any other asset could be included.

After a farmer has chosen A and F, the state of nature—which is the profitability of the crops, x, and the gains or losses from the futures positions, z—is revealed. The returns from a futures position are the brokerage fees and interest on margin, which are likely to be small,[1] and the loss (or gain) from the futures position itself. Without predictive ability on the part of farmers, the Keynes-Hicks-Cootner theory of speculative markets holds that storers and producers of commodities will pay speculators to take the price risk of holding commodities. Indeed, this loss on futures, which can run several cents per pound for cotton (and is assumed away in Peck's work on eggs), provides a major reason for farmers not to hedge.[2] On the contrary, if farmers have good predictive ability, then they may enter the futures market for the same reason as speculators—to make an (expected) profit on their futures position.

The farmer's second-period income, Y, is composed of profits from crops, losses (or profits) from futures, interest cost on credit, interest paid on deposits, and interest paid on fixed debt:

$$(3) \qquad Y = x'A + z'F + rB - rD.$$

From this expression and the definitions of $\tilde{x} = x - \bar{x}$ and $\tilde{z} = z - \bar{z}$, where the bars denote the means and E is the expectation operator, one can calculate the mean, M, and variance, V, of income for given futures and cropping plans:

$$(4) \qquad M = \bar{x}'A + \bar{z}'F + rB - rD;$$

$$(5) \quad V(A, F) = A'E(\tilde{x}\tilde{x}')A + F'E(\tilde{z}\tilde{z}')F + 2A'E(\tilde{x}\tilde{z}')F.$$

Equations (4) and (5) show that debt payments, rD, give any crop futures plan a lower mean for a given variance or, in common parlance, greater risk.

A point on the mean-variance frontier with variance, V^*, corresponding to mean, M^*, is computed by choosing A and F to minimize $V(A, F)$ subject to equations (1), (2), and (4). Letting λ shadow the land constraint, γ the

---

[1] With a sympathetic banker who will lend money at close to prime (so that cost of the money is the prime rate less the rate on treasury bill posted as margin) and who will not impinge on the farmer's other credit lines, the cost of credit will be small. With a discount broker who will charge about $20 for a "round turn," the brokerage fees will be small.

[2] Peck considered using regression equations for prediction of futures mean-square error in her study of eggs. She credits Fried with the idea. In fact, she assumed the mean return of egg futures was zero, and she estimated the mean-squared error from the differences of a predicted and actual series.

credit constraint, and α the mean constraint, the Lagrangian for this problem is

$$L = -V(A, F) + \lambda(L - a'A) + \gamma(W - f'F - B) - \alpha(M^* - \bar{x}'A - \bar{z}'F - rB + rD).$$

The interesting Kuhn-Tucker conditions are[3]

(6) $L'_A = \alpha\bar{x}' - 2(A'E[\tilde{x}\tilde{x}'] + F'E[\tilde{z}\tilde{x}']) - a'\lambda \leq 0$, and $L_{A_i} \times A_i = 0$ for every i;

(7) $L'_F = \alpha\bar{z}' - 2(F'E[\tilde{z}\tilde{z}'] + A'E[\tilde{x}\tilde{z}']) - \gamma f' \leq 0$, and $L_{F_i} \times F_i = 0$ for every i;

(8) $L_B = \alpha r - \gamma \leq 0$ and $L_B \times B = 0$.

Noting that $A'\tilde{x} - F'\tilde{z}$ is the stochastic portion of income, $\tilde{Y}$, equation (6) states that either a crop is not grown or, at an optimal portfolio, its mean return times the rate of technical substitution of mean for variance, α, equals twice the covariance of the crops return with income, $\tilde{Y}$, and the shadow cost of land. Equation (7) has a similar interpretation. Both equations include the covariance of an activities return with the whole portfolio, so one needs to know the covariance of all the crops and futures, not just crops with their own futures.

The set of all efficient points makes up the mean-variance frontier. Any agent with a mean-variance utility function will select an (interior) point on the frontier at which his rate of commodity substitution of mean for variance equals the rate of technical substitution. These variances, covariances, and means are computed in the next section.

Means and Variances

An estimate of the means and variance-covariance matrix of the returns from crops and futures is required for the computation of the efficient set. This estimate is constructed (instead of by variate differencing) by applying Seemingly Unrelated Regression (SUR) technique (Thiel, p. 297) to a set of equations describing the quasi-rents of the crops and the returns from futures holdings (Fried). The SUR prediction error estimates the variances, $E\tilde{z}\tilde{z}'$, $E\tilde{z}\tilde{x}'$, and $E\tilde{x}\tilde{x}'$, while the SUR prediction estimates the means, $\bar{z}$ and $\bar{x}$, both conditional upon the opening futures prices and previous years' yields. This conditional mean-variance frontier describes the mean-variance trade-off with complete annual revision of the cropping pattern. This is not strictly true for Kern County because much of the cost of growing alfalfa is the establishment of stands that can last five years. Nevertheless, the conditional frontier is a better estimate of the choice set than the unconditional frontier which would be appropriate if all the crops had to be assigned the same acreages year after year. The remainder of this section reports the crop and futures equation.

Crop Equations

Because data on inputs are sparse and the cost data are often crude, crop quasi-rents were predicted from linear regression on a constant, expected cost and the product of expected yields and expected price. There is a futures price for cotton for the whole period and potatoes for half the period, so price expectations for these crops are taken as the futures price times a constant to account for backwardation. For the remainder of the period for potatoes and for beets and cottonseed, a lagged price times a constant to account for inflation is used. For alfalfa and barley, the wheat futures is used with a constant to account for the relation between wheat and the other crop price and for backwardation.[4] Thus, the regression coefficient on expected revenue contains both the effect of revenue on quasi-rent and the effect of backwardation, inflation, etc., on price expectations. A dummy variable was included in the potatoes regression to account for the two different estimates of price expectations.

Table 1 contains the definition of the variables and their sources. Preliminary investigation did not give the expected signs on the sugar beet equation so that the equation was split into separate cost and revenue equations. After estimation, this cost equation was subtracted from the revenue equation to provide an unbiased, if not efficient, estimate of π.

[3] The other Kuhn-Tucker conditions are the nonnegativity of B, A, F, λ, γ, and α; equations (1), (2), and (4); and complementary slackness.

[4] The problem with corn, which seems the more natural choice, is that it is harvested too early in the season to be well-timed with respect to the bulk of the alfalfa cutting or barley harvest. What it gains in closeness as an animal feed, it loses in timing. Note that B now contains the constant of proportionality.

Both the alfalfa and barley quasi-rent regressions gave good fits and correct signs:

$$\begin{array}{llll} \pi_{Alfalfa} = & 79.53 + & 7.63\, P^eY_F{}^e - & .72\, C^e, \\ & (15.36) & (0.94) & (0.09) \\ & (5.18) & (8.15) & (8.07) \end{array}$$

where $R^2 = .79$;

$$\begin{array}{llll} \pi_{Barley} = & 7.28 + & 12.80\, P^eY_F{}^e - & .54\, C^e, \\ & (37.23) & (2.49) & (0.44) \\ & (0.19) & (5.15) & (1.24) \end{array}$$

where $R^2 = .49$. In both cases, the t-ratios (first the standard errors and then t-ratios are reported in parentheses under the coefficients) for P^eY^e were quite high, indicating success in predicting barley and alfalfa prices from wheat futures, but the magnitudes of the coefficient are uninterpretable because they contain the conversion from wheat to other crop price. The lagged cost coefficients should be close to and above minus one because of the slight downward trend in real costs, but in these equations the cost coefficients are a little too high.

The cotton equation contains a variable for both predicted seed revenue $(P^eY^e{}_{L-Seed})$, based on a lag, and lint revenue, based on the futures price $(P^eY^e{}_{F-Lint})$.

$$\begin{array}{llll} \pi_{Cotton} = & 758.29 + & .95\, P^eY^e{}_{F-Lint} & \\ & (124.23) & (0.11) & \\ & (6.10) & (8.32) & \\ & & + 1.49\, P^eY^e{}_{L-Seed} & -3.66\, C^e, \\ & & (0.41) & (0.42) \\ & & (3.63) & (8.82) \end{array}$$

where $R^2 = .89$. Although all coefficients were of the right sign and significant, the expectation that the coefficient of $P_eY^e{}_{F-Lint}$ would be greater than one (a change in price would increase both yield and price and backwardation) was not borne out, and the coefficient on the cost variable was too low. Nevertheless, the high R^2 and t's make this a good equation for prediction purposes.

Root crops are widely believed to be risky, and the equations for sugar beets and potatoes bear this out with large prediction errors, low R^2, and a general lack of significance in the coefficients:

$$\begin{array}{llll} \pi_{Potatoes} = & 243.67 + & .46\, P^eY_F{}^e + & .23\, P^eY_L{}^e \\ & (761.41) & (0.12) & (0.18) \\ & (0.32) & (3.78) & (1.23) \\ & & + 573.97\, Dum - & 1.16\, C^e, \\ & & (310.27) & (1.10) \\ & & (1.85) & (1.05) \end{array}$$

Table 1. Definitions and Sources of Variables For Crop Quasi-Rent Equations

C	For each crop, deflated per acre variable costs from harvest and preharvest plus equipment and irrigation interest and depreciation, excluding charges for land. For alfalfa, ⅓ of the cost of stand establishment is included.
C^e	Previous year's cost.
R	Value of production divided by harvested acres, deflated.
π	$R - C$.
$P^eY_F{}^e$	Once-lagged, three-year moving average of yields per acre times a deflated futures price (for alfalfa and barley, 15 December price for September wheat; for cotton lint, 15 April price for December cotton; for potatoes, 15 January price for May potatoes only for 1969–1977).
$P^eY_L{}^e$	Once-lagged, three-year moving average of yields per acre times once-lagged deflated price received by farmers (for cotton seed, potatoes, and sugar beets).
DUM	A dummy variable. 1 for 1963–1968, 0 otherwise.

where $R^2 = .59$.

Futures

The futures strategies considered are those most appropriate to a grower: the sale or purchase at planting time of futures that mature slightly after harvest.[5] Provision is made for trading after a prespecified price change as a crude way of accounting for limited credit and for a mean-variance decision maker's disproportionate concern with large price swings. For both of these reasons, futures are imagined to be purchased with a stop-loss order varying between 4¢ and \$1.00 per unit (pound or bushel). For example, 50,000 pounds (one contract) of cotton sold with a 25¢ stop-loss amount (SLA) requires a \$12,500 line of

[5] If the decision process is viewed strictly as a one-decision point process, then the prices should all have the same date as the decision point.

credit. If the futures rises 25¢, the contract would be repurchased. These stop-loss orders allow the construction of complicated strategies that start speculative and end as hedges such as two long contracts with a 10¢ stop loss and one short contract. On a price rise, the position remains net one long; on a price fall, it reverts to one contract short (and a loss of 10¢ per pound times two contracts or $10,000 for cotton).

The mean and variance of holding futures were estimated by linear regression of futures gains on a constant and are reported in table 2. The Keynes-Hicks theory of backwardation with the "Cootner wrinkle" holds that during the period consumption comes from storage, the price of futures should rise, effecting a risk premium paid by storers to speculators. The regression results show this risk premium as an expected loss to the short position. The lack of significance (low t-ratios) was cited as evidence against the Keynes-Hicks-Cootner theory by Telser and others. In this formulation, high t-ratios would imply almost certain profits from holding a long position, so the low t-ratios are almost expected. Adding other variables, such as planting intentions or opening price, does not improve the predictive power of the equations.

Empirical Results

We used quadratic programming to construct the mean-variance frontier from the estimates of mean and variance constructed above and the opening futures prices for 1978. This section describes the cropping plans and futures holdings along this frontier. It gives two ways of choosing a point on the frontier and evaluates the effect of fixed debt on the optimal choice. It shows that the benefits of simultaneous choice of crops and futures are quite large and that the simultaneous choice has a large effect on the amount of hedging. Finally, it shows that the price of hedging is a significant determinant of the amount hedged and that forecasting can make a difference.

The Frontier

The mean-variance frontier starts with less risky and moves to more risky crops while going from hedge to speculative futures positions. The quadratic programming results show that at low mean returns (about $120 per acre), cotton and alfalfa are grown; about 16% of the cotton is hedged against a price drop of more than 25¢ per pound. Although barley is also a low-risk crop, it is omitted from the portfolio because it was projected to cause losses in 1978. Moving up the mean-variance frontier entails substituting sugar beets for the cotton and changing the futures position to a more speculative stance. In the data, going long in cotton has an expected positive return and a mean-variance trade-off somewhat comparable to growing sugar beets; so, by the time mean income reaches $200 per acre, the futures position is to speculate in cotton. The positions advocated in the sugar beet portion of the mean-variance frontier are suspect because of two peculiarities in the data: (a) the cost of growing sugar beets is suspect and

Table 2. Regression of Gains from Holding a Futures Contract on a Constant Term

probably too low (Thor) and (*b*) the sample wheat futures and sugar beet profits have the large correlation of $-.5$, leading to the cross-hedging of sugar beets in the wheat market. Although it is hard to accept the recommendation that sugar beets be grown, a number of other crop combinations currently grown in Kern County could fill the expected high profit, mildly speculative niche: to name a few, carrots, garlic, soybean-barley double crop, tomatoes, and dry beans.

The further reaches of the mean-variance frontier are characterized by a potato-cropping system. Because early potatoes are a very risky, perishable fresh vegetable, very few operators (34 in the Bank of America sample of 1,028 cited by Pope) grow them, although these growers are each so large that potatoes are the largest acreage vegetable in Kern county. Potatoes are not hedgeable because the contracts traded are for Maine and Northwest potatoes and correlate almost not at all ($-.01$) with Kern potato profits. Moreover, the trade between mean and variance is so extreme at the point on the efficient set where potatoes are grown that outright speculating in cotton—up to the available credit limit—is part of the efficient portfolio.

Choosing a Point on the Frontier and the Effect of Debt

The evaluation of risk is the choice of a point on the mean-variance efficient set, either by a utility function written explicitly in mean and variance or by safety-first criteria. For instance, letting M be the mean and V be the variance, $\ln(M) - 100V/M^2$ is a mean-variance function. Figure 1 shows the tangency of a level curve of this mean-variance utility function to the mean-variance frontier at a mean of \$175,050. So, an agent with this mean-variance utility function would select the cropping and futures plans associated with a mean income of \$175,050. When the problem is altered to include a fixed debt load of \$80,000 (1,000 acres at the cheap price of \$1,000 per acre—80%—financed by a 10% mortgage), the optimal point on the frontier has mean \$370,000. Another way to view mean-variance frontiers is to convert the efficient set to a safety-first statement through

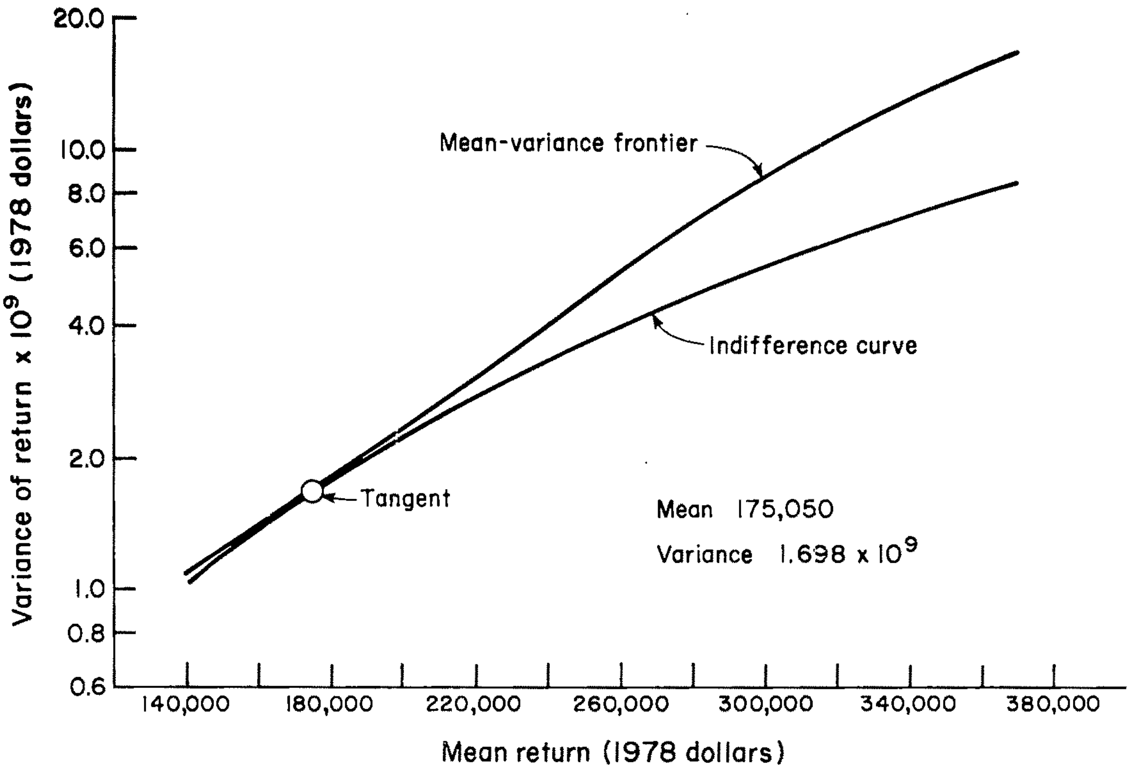

Figure 1. An indifference curve of a mean-variance utility function tangent to the mean-variance frontier

the Chebychev inequality, prob $(Y < M - k\sqrt{V}) < 1/k^2$, or a new variant (Berck and Hihn) of the inequality in terms of semivariance, SV, prob $(Y < M - k\sqrt{V}) < SV/(k^2V)$.[6] Using the semivariance Chebychev bounds, the probability of meeting a fixed payment of $80,000 increases as the mean return increases until the mean return is $233,000 and probability of success is 93%; it decreases thereafter. To break even (zero payment), the safest mean return is about $140,000. In these examples, which are two of many ways of selecting a mean-variance efficient point, fixed debt leads to the selection of riskier plans.

Benefits of Diversification

Table 3 shows that adding activities to the choice set substantially reduces the variance that must be incurred to achieve a given level of mean income. A comparison of the first two columns of the table shows that adding other crops (primarily sugar beets) to the alfalfa-cotton cropping system reduces the variance for a given mean by about one-third. For instance, at a mean income of $115,700, the cotton-alfalfa system's variance of income is 2.27×10^9, while the all-crops system's variance is only 1.44×10^9. Similarly, a comparison of the columns labeled "All Crops" with that labeled "All Crops and All Cotton Futures" shows that for all but extreme mean returns, the addition of both speculative and hedging possibilities in cotton futures does very little to improve the mean-variance trade-off. Finally, comparing the last two columns of the table shows that adding the other hedging and speculative possibilities—primarily wheat futures—again vastly decreases the variance for given mean. This final decrease in variance, however, is at least partially based on the high (and suspect) sample covariance between the profits from growing sugar beets and a short position in the wheat market. The appropriate conclusion is that both diversification of crops and the adoption of complicated hedging strategies significantly improve the mean-variance trade-off.

Effect of Diversification on Hedging

In addition to improving the mean-variance trade-off, the addition of activities to the choice set also changes the cotton-hedging strategy. The hedging strategy used by both Peck and Rolfo is based on the covariance of cotton and cotton futures. As shown in the first column of table 4, the strategy is to hedge 8.9% of the cotton crop for points of the efficient set corresponding to a low mean return and to decrease the hedge to zero for high mean-return points. Comparing the first column of the table to the second column (labeled Alfalfa, Cotton, and All Cotton Futures) shows the effects on the futures positions of allowing complicated hedging strategies with stop-loss orders and of including the covariance of the futures with alfalfa quasi-rents. The correlation with alfalfa increases the size of the hedge because the cotton hedge is negatively correlated with both cotton and alfalfa quasi-rents. The columns labeled "Initial" and "Deep Hedge" refer to the position taken on planting and the position taken when

[6] Let x have the cumulative distribution F with mean $\bar{x}$.

$$SV = \int_{-\infty}^{\bar{x}} (x - \bar{x})^2 dF.$$

Table 4. Percentage of Cotton Hedged by Mean Return For Three Sets of Activities, Computed

	Cotton and *SCOT50*	Alfalfa, Cotton, and All Cotton Futures		All Crops and All Futures	
Mean Return	Hedge	Initial Hedge[a]	Deep Hedge[b]	Initial Hedge[a]	Deep Hedge[b]
116,700	8.9	11.3	11.3	−8.4	6.1
155,000	8.9	−1.7	99.5	−8.4	6.1
175,000	1.4	−30.5	116.1	−10.4	3.3
194,000	[c]	−32.9	136.2	−12.6	5.4

Note: Negative signs indicate a long or speculative position.
[a] Position taken before any price changes.
[b] Position taken on 25¢ price drop.
[c] This mean cannot be achieved.

prices fall by 25¢, respectively. Futures positions that begin long but revert to a hedge on a large price fall allow speculation without the risk of large losses. When crops other than cotton and alfalfa and futures other than cotton are added to the crop mix, the last two columns of table 4 show the hedging strategy in cotton. Even at low mean returns, the initial position is now speculative, but the position after an adverse price fall is now only a mild hedge, less in fact than the Peck-Rolfo hedge. Apparently, other futures and other crops are more effective in diversifying the risk of the cotton-alfalfa system than are the cotton futures. Indeed, as this example shows, the choice of futures holding in a mean-variance framework is very sensitive to what activities other than own-crops and futures are included in the portfolio choice set.

Price of a Hedge

The price or "risk premium" of a hedge is the expected loss from selling the futures. A short position in cotton loses 9.3¢ per pound or about half of the per pound profits of growing cotton. The demand for hedging can be traced out by varying its price or risk premium and recording the consequent demand for hedging. In a $124,000 expected income plan in which only cotton and alfalfa are grown and the only future is the hedge SCOT50, a 1¢ change in the risk premium results in a 9/10% change in the percentage hedged. If the hedge were costless, the percentage hedged would double; but it would still be quite low. More complicated hedging strategies require a decrease in the profitability of the long position at the same time the "risk premium" of short position is decreased so that there are no certain profits from taking offsetting positions. Figure 2 shows the demand curves for hedging cotton in an all crops and futures activity choice set except LCOT10, SCOT10, and SCOT25. At an expected return of $155,600, the hedge more than doubles if the risk premium is eliminated, while at an expected return of $194,500 the ratio is closer to fifteen times. As these experiments show, the size of the risk premium has a large effect on the percentage of the crop hedged.

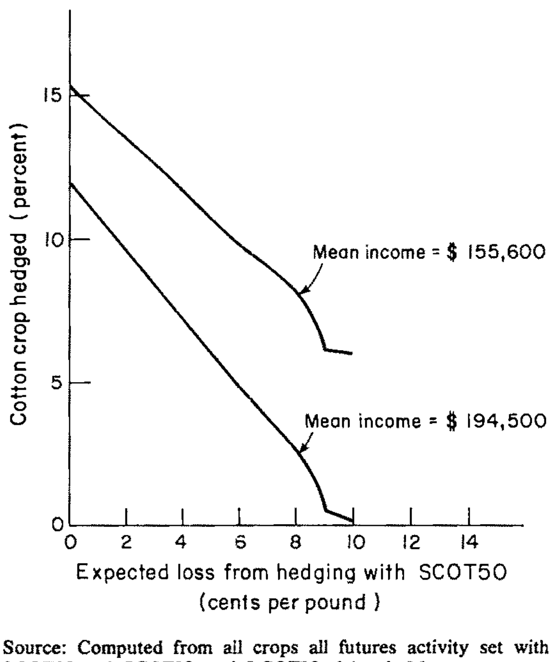
Forecast

This model does not do justice to forecasting because the futures price is used to forecast crop prices. A prediction of a smaller loss than the model predicts is a narrowing of the difference between the observed futures price and the expected price at the settlement time and is analogous to a prediction of a lower cash price than is predicted in the model. It leads to a greater hedge position (see fig. 2).

Conclusion

The empirical section verifies what the theory section postulates—that the costs of hedging and the opportunity to diversify risk by growing other crops substantially change the optimal hedge and opportunity set for California farmers. Although commodity exchanges want the additional hedging volume that could be generated by farmers, educating cotton farmers will not produce such additional volume: the price of hedging is high enough so that storers of cotton who have no yield risk find hedging worthwhile, but producers whose yield risk makes this insurance imperfect find the price too high.

Because this paper considers only a planting-time hedge, it leaves unsettled the optimal path for a hedge to take between planting



Source: Computed from all crops all futures activity set with SCOT25 and SCOT10 and LCOT10 deleted. Mean returns to LCOT25 were decreased by $.004 for each $.01 change in SCOT50.

Figure 2. Demand for hedging (percent hedge by expected loss per pound)

and harvest. At planting time, there is yield risk. As the crop year progresses, that risk is resolved until, at harvest, the producer has no yield risk. He is just the same as any other storer. It is reasonable that the hedge should evolve over the crop year from that appropriate to a producer to that appropriate for a storer. The mathematical tool for investigating the influence of new information on hedging is open-loop control which is well known. However, there is a twofold empirical problem: (*a*) constructing a yield prediction model that is updated as the crop progresses and (*b*) constructing a price prediction equation not wholly dependent upon the futures price. Such a model can point the way to the profitable use of futures by farmers.

Empirical Analysis of Soviet Agricultural Production and Policy

Michael L. Wyzan

This paper employs production function analysis to examine a number of pivotal issues concerning the Soviet agricultural sector. Estimates of three input translog production functions for five agricultural commodities grown in the Soviet Union from 1960–76 are reported. These results are used to draw inferences on such matters as the rationality of Soviet agricultural factor pricing, the nature of agricultural returns to scale in the USSR, and the scope of factor substitution in that country. The empirical evidence suggests that Soviet decisions in the sphere of agricultural production, contrary to the conventional wisdom, are well-founded technologically.

Key words: kolkhoz, New Lands Program, partial elasticity of substitution, pooled cross-section time-series data, returns to scale, Soviet Union, *sovkhoz,* specification error.

The estimation of production functions is in many instances a powerful tool for examining important matters of economic policy. In this paper, three input translog production functions are estimated for five Soviet agricultural commodities. The estimation is performed on a data set gathered by the author from official Soviet statistical publications. The data contain information on output, land, labor, and capital, measured in physical units, covering grain, sugar beets, cotton, potatoes, and vegetables grown in the Soviet Union during the seventeen-year period, 1960–1976.

The results are used to draw inferences concerning various important aspects of Soviet agricultural policy. Although outputs are derived from inputs within a great variety of institutional structures (Western market orientation, Soviet command mechanisms, Yugoslav self-management, and so on), all such schema are ultimately constrained by the physical technology of production.

Accordingly, the rationality of Soviet factor pricing can be examined by looking at productive relationships in purely physical terms. Because the idiosyncracies of Soviet factor pricing always result in prices which are "too low," we would expect certain factors to be relatively "overused." Hence, it might be asserted that the more the pricing of an input deviates from neoclassical input pricing, the likelier it is that its marginal product will be insignificantly different from zero. Evidence relative to this hypothesis is presented below.

As a second example of the relationship between productive technology and economic policy, we might consider returns to scale. It has been common in the literature on Soviet agriculture to assume that the Soviet penchant for large farms is unjustified on technological grounds; that is, that returns to scale in agriculture are generally rather small (Bradley and Clark). Yet evidence as to the actual magnitude of scale effects has rarely been presented; such evidence is reported in this paper.

Results also are presented concerning the nature of factor substitution in Soviet agriculture. Previous work on Soviet productive technology has indicated that factor substitution in the Soviet industrial sector is quite limited (Weitzman). Our findings for the agricultural sector are interesting not only in comparison with these results, but also because they have important implications for evaluating certain specific Soviet policies. These include the New Lands Program of the Khrushchev era and the impact of the intro-

Knox Lovell, David Guilkey, Elizabeth Clayton, and the people at the Foreign Demographic Analysis Division of the Commerce Department for various types of assistance. All statistical computations were performed using the Statistical Analysis System.

duction of new vintages of equipment on factor productivity.

The paper is organized as follows. The first section is a discussion of the data set and some related econometric matters. The second briefly describes the properties of the translog production function. The third section presents the results and outlines their implications for a variety of policy issues, and the last provides some concluding remarks.

Data and Econometric Considerations

Because the data set was gathered by the author, innumerable matters concerning its format and peculiarities might be mentioned. Considerations of space preclude all but the most cursory description thereof. The data were obtained at the Foreign Demographic Analysis Division (FDAD) of the U.S. Department of Commerce. FDAD maintains an outstanding collection of official Soviet statistical publications on the Soviet Union and Eastern Europe, without which empirical work on this vital geographical area would be quite difficult.

As mentioned in the introduction, figures are available for five crops, grain, sugar beets, cotton, potatoes, and vegetables. Other crops (especially sunflowers, flax, and fodder crops) and livestock products are not included because there are no published data on labor inputs into their production. The data on each crop are in the form of a pool of cross-sectional and time-series observations, with each time-series covering some fraction of (and in some cases, all of) the period, 1960–1975. The cross-sections are formed by union republics (of which there are fifteen) and sometimes also by types of enterprise (collective farm or state farm) within republics. Because of the uneven availability of the requisite figures, the time-series are of varying lengths, ranging from a full seventeen years for grain in the Russian republic to seven years for cotton in Turkmenistan. In total, there are 999 cases, 323 for grain, 199 for sugar beets, 101 for cotton, 229 for potatoes, and 147 for vegetables.[1]

All data come directly from official Soviet statistical publications, either national or republican, and are not qualitatively adjusted (the most recent national publication is *Tsentral'noe Statisticheskoe Upravlenie*). For output and all inputs, the figures are broken down by crop, year, republic, and, generally, type of farm. Land is measured in thousands of hectares of "sown area," defined as the productive area in the spring, as recorded at the end of the spring sowing. A word is in order on variation in land quality across republics, a phenomenon expected to be quite important in such a large country. It was stated above that none of the data is qualitatively adjusted. Two pieces of evidence may be cited in support of our decision not to adjust the land data. First, regional dummy variables included in estimated (translog) production functions all prove to be statistically insignificant for every crop. Second, Clayton (p. 453) reports that her own qualitatively adjusted Soviet land data, when employed in an aggregative production function, give insignificantly different results from unadjusted data in that function.

Labor inputs are measured in thousands of man-hours, similarly broken down. The statistical publications provide these numbers as labor intensity data—man-hours per unit of output. Data on labor inputs are easily obtained by multiplying the intensity figures by an appropriate physical weight measure of output. Output figures are available in thousands of metric tons.

Capital services are measured by proxy. No crop-specific Soviet capital data are available or have even been suggested by previous studies. In work in other areas, electricity usage has served as a proxy for capital, under the (plausible) assumption that the flow of capital services is in roughly fixed proportion to the use of electricity in a given time period (Moody). In this study, because electricity data, broken down by crop, are unavailable, the number of a certain type of machine in existence in each year serves as the proxy. Grain combines serve this purpose in grain cases, cotton machines in cotton cases, and tractors in all other cases. A good argument can be made for machine numbers being a reasonable proxy for the entire input of capital into the production of the respective crops.[2]

[1] An appendix detailing the data-gathering process is available upon request from the author. See Wyzan, chap. 2, on which this discussion is based. The crop categories sugar beets, cotton, and potatoes are homogenous; "grain" consists primarily of wheat, barley, oats, rye, corn, pulses, millet, rice, and buckwheat. "Vegetables" are composed mostly of cabbages, tomatoes, cucumbers, onions, carrots, and beets.

[2] Tractors are used in vegetable cases because there seems to be no piece of capital equipment specific to their production. Although some figures are available on beet combines and potato combines, such data cannot be obtained for all cases. In the

Before moving on, two econometric matters deserve mention. The first comes under the general heading of specification error, and, more specifically, the measurement of capital by proxy and the omission of some important inputs, such as fertilizer, irrigation, and seed. The second concerns the fact that the data set is what might be called an "unmatched" pool of cross-sectional and time-series observations.

In the following discussion, it is assumed that we are dealing with a log-linear functional form, such as the Cobb-Douglas or translog function. The specification problem may be summarized by noting that instead of having available the correct Txk matrix of observations on k independent variables, X, we have Z. The latter is a matrix differing from X either in dimension, if there are observations on fewer than k regressors, or in the numbers in one of its columns, if one of the regressors is measured by proxy (among other reasons), or both. It is well-known that the estimated coefficients of the z's are biased and inconsistent estimators of the true coefficients of the x's (Griliches).

Let M be the proxy related to the true measure of capital services, K, by

$$M = K\theta + \mathbf{e}, \tag{1}$$

where θ is a fixed but unknown parameter and $\mathbf{e}$ is a vector of well-behaved disturbance terms. As just noted, the use of M biases the estimates of the output elasticities of all the inputs. However, it has been shown that the asymptotic bias to our estimates of the output elasticities of land and labor caused by using M is less than that caused by not having any measure of K at all, under most circumstances. These circumstances include whenever land and labor are measured without error, as well as cases in which they are inaccurately measured, but the output elasticity of capital is not "close" to zero (Barnow, Aigner). Because we have reason to believe that our land and labor data are relatively accurate, and because the conventional wisdom on proxy variables is to include one when you have it, we seem to be on firm ground in our use of a proxy.

We turn next to the question of missing independent variables. If there is just one omitted variable, say, fertilizer, the bias to the estimated output elasticity of each input is the product of two numbers. The first is the regression coefficient on that input which would result if fertilizer were used as the dependent variable in an "auxiliary" regression on the other three inputs. The second is the output elasticity of fertilizer in the correctly specified production function.

If we are safe in assuming a positive output elasticity for fertilizer, the correlation between a particular input and fertilizer inputs determines the sign of the bias to the estimate of the output elasticity of that included input. In a time-series data set, of course, correlations between independent variables depend upon whether the given variables are growing, declining, or remaining unchanged. In this particular data set, land inputs remain fairly unchanged over the period, labor inputs decline at about 2% annually, and capital inputs rise at approximately 5½% per year. Deliveries of fertilizer grew at a fairly rapid rate. We therefore expect the output elasticity of capital to be overestimated, that of labor to be underestimated, and little bias to the estimated output elasticity of land.

Fortunately, we do have some evidence to corroborate these conjectures. All of the production functions reported below were estimated with and without a time index denoting neutral technical progress. The inclusion of such a term should take account of some of the effects of excluded inputs, the applications of which have been growing over time. In fact, the notion of technical progress may be merely a convenient way to capture the effects of the absence of some inputs and the mismeasurement of others (Griliches and Jorgenson). Evidence reported below is highly supportive of these assertions.

A word is also in order on the status of the data set as a pool of cross-sectional and time-series observations. As noted above, the data set on each crop consists of a group of concatenated time series of varying lengths. Each series consists of observations on a particular republic and covers a period which varies in length from seven to seventeen years. For nine of the fifteen republics, there are two such series, one for collective farms and one for state farms.

Ideally, one would employ the seemingly unrelated regressions technique, with each republic as a separate equation, and use the results to test whether or nor pooling the data is statistically justified. If it is decided to pool the

absence of the knowledge of an equivalency factor between tractors and the relevant type of combine, it was deemed best to use tractors everywhere.

data, further statistical means can be used to take into account various disturbance structures. Unfortunately, the usual methods of doing this are unavailable when the time series are of different lengths (Zellner).[3] In the end, therefore, the entire group of observations on a crop, with no account taken of the particular year, republic, or type of farm which a particular observation represents, is used in the estimation of the production function for that crop.

The Translog Production Function

The three-factor translog production function employed in this study is written,

$$\begin{aligned}(2)\quad \ln y_i = {} & b_0 + b_1\ln R_i + b_2\ln L_i + b_3\ln K_i \\ & + b_4(\ln R_i)^2 + b_5(\ln L_i) + b_6(\ln K_i)^2 \\ & + b_7(\ln R_i)(\ln L_i) + b_8(\ln R_i)(\ln K_i) \\ & + b_9(\ln L_i)(\ln K_i) + \epsilon_i,\end{aligned}$$

where the subscript i indexes a particular observation, y is output, R is land, L is labor, K is capital, and ϵ, the vector of disturbances, satisfies the usual conditions (Berndt and Christensen). Results using the Cobb-Douglas, constant-partial-elasticity-of-substitution, and transcendental production functions are contained in Wyzan, appendix 2.

Although it also can be viewed as an exact representation of the productive technology, the translog function is best seen as a second-order Taylor series expansion around the means of output and of each input. It is chosen because it allows the researcher to estimate the nature of returns to scale and factor substitution, instead of imposing a priori restrictions on them. Furthermore, regions with nonconvex isoquants (noneconomic regions) exist whenever any coefficient b_i $(i=4, \ldots, 9)$ is estimated to be significantly different from zero. (If none is, the function reduces to the Cobb-Douglas form.) Finally, neutral technical progress is easily taken into account by letting

$$(3)\qquad y = e^{\lambda t}h(R,L,K),$$

where

$$h = e^{b_0}R^{(b_1+b_4\ln R+b_7\ln L+b_8\ln K)}L^{(b_2+b_5\ln L+b_9\ln K)}K^{(b_3+b_6\ln K)},$$

and t is a time index equal to 1 for the first year of the data set, 2 in the second year, and so on. We can therefore estimate

$$(4)\qquad \ln y = \lambda t + \ln h.^4$$

Results and Analysis

We turn now to the presentation and analysis of the empirical findings. In table 1, the coefficients of the translog production functions estimated for each crop without a technical progress term are presented. In table 2, similar results are reported for each crop, in this case with neutral technical progress taken into account. Table 3 reports the estimates of returns to scale and of each of the partial elasticities of substitution. σ_{ij} refers to the partial elasticity of substitution between inputs i and j $(i,j = R,L,K, i \neq j)$. The figures refer to the mean values of these effects, found by first evaluating the relevant effect at every point in the data set on a crop, and then determining the arithmetic mean of these calculations. These elasticities are of the Allen-Uzawa variety and are calculated according to a formula given by Berndt and Christensen (p. 97).

The estimates shed light on a number of interesting policy questions. Before exploring these areas, a couple of technical matters deserve mention. First, recall that if none of the coefficients $b_4, \ldots b_9$, is estimated to be significantly different from zero, the translog function reverts to the Cobb-Douglas function. Note from table 2 that, for grain and sugar beets, (when technical progress is included), none of these coefficients is significant. In the cases of the other three crops, at least one such coefficient is significant. This may be taken as evidence that the translog function is not always (for all crops) superior to the Cobb-Douglas function. One must keep in mind, however, that multicollinearity undoubtedly has raised the standard errors of the coefficient estimates. For this reason, in addition to the numerous advantages cited above, the translog function remains our preferred functional form.

Second, it is useful to compare the estimated coefficients on the logarithms of land, labor, and capital for each crop between the

[3] Actually, Schmidt has shown that it is possible to get satisfactory results by ignoring the "extra" observations when estimating the covariance matrix. The vastly divergent lengths of the time series within our data set precluded using this result, however.

[4] Some problems with the translog function include the possible existence of multicollinearity among the regressors, specification error caused by the fact that it is only a second-order approximation, and the fact that, like any Taylor series expansion around a point, it may be a poor approximation to the true function far from that point.

(sugar beets, potatoes, and vegetables) have negative elasticities of land—an impossible result when an optimizing land purchaser faces positive rents but quite possible here. Farms are so large and generally grow such a variety of crops that land inputs to a particular crop can increase considerably and, perhaps, inordinately. This may well have happened for these three, not usually land-intensive, crops.

Capital pricing is a complex matter, intermediate in "rationality" between labor and land pricing. The extension of credit to farms has grown in recent years, and physical capital services are a component (if an arbitrarily calculated one) of cost (Morozov, pp. 99–101). In our results, capital has a positive elasticity for all crops, but an insignificant one for sugar beets and cotton. This intermediate finding for capital correlates well with the intermediate rationality of capital pricing. In sum, our hypothesis seems to be well-founded.

Another interesting matter is the question of the estimated mean returns to scale, as reported in the first column of table 3. They are surprisingly large, being greater than one for all crops but sugar beets. In fact, the crops exhibiting the largest scale effects are vegetables and potatoes, two commodities not generally thought to be characterized at all by increasing returns.

Our data set, being essentially an aggregative (over farms) time series, is less than ideal for measuring returns to scale. Care must be taken in interpreting these results, because larger input vectors may only mean a larger republic (in a cross-sectional context) or growth due to addition of new farms (in a time-series context). Even so, estimating scale parameters from aggregative data sets is hardly unusual in economics. These results are interesting, especially in view of the assertion of Bradley and Clark that, despite Soviet attempts to do so, farms cannot be run efficiently on large scales imitative of industrial enterprises. They cite as evidence several factors, all of which center on the difficulty of supervising a large labor force in an agricultural setting. These include the sequential nature of production, the fact that the results of work in the planting stage cannot be observed until several months later when it is difficult to determine responsibility for failure, and the physical dispersion of tasks. Our finding of high estimated returns to scale in Soviet agricultural production must be taken as evidence against the Bradley-Clark hypothesis.

The next topic is the mean estimated partial elasticities of substitution ("substitution elasticities"), presented in table 3. These estimates, as is well-known, have major implications for the potential growth of the output of the crop to which they apply. Since the weight of each input in the (percentage) growth rate of output is its output elasticity, it is of interest to know what happens to these output elasticities as relative factor intensities change, knowledge derivable from the partial elasticities of substitution.

If the partial elasticity of substitution between any two factors is between zero and one, the size of the output elasticity of the faster-growing factor relative to that of the other factor decreases. The opposite pattern of change occurs under two circumstances. It happens when the partial elasticity of substitution between two inputs exceeds one; in this case, the relative increase in the usage of the faster-growing factor is larger than the relative decrease in its marginal productivity. It also occurs when the partial elasticity of substitution is negative (the factors are complements). Here, the relative marginal productivity of the faster-growing factor actually increases with its relative usage.

Weitzman (and others) have found in two-input studies that a low (positive) elasticity of substitution between labor and capital exists for the Soviet industrial sector (Weitzman). When this result is combined with the fact that capital inputs are growing rapidly while labor inputs are (at best) stagnant, a relative decline in the output elasticity of capital is implied. Hence, capital's contribution to output growth shrinks as production becomes more capital-intensive; while labor's weight rises, future growth of labor resources is unlikely under present Soviet demographic conditions. All of this bodes ill for future industrial output growth.

Can similar results be found for the agricultural sector? We know that capital inputs to this sector have been rising fairly rapidly, labor inputs declining slowly, and land inputs have been fairly unchanged. Note from table 3 that twelve of the fifteen substitution elasticities are either greater than one or less than zero. Because such elasticities imply a rising output elasticity for the faster-growing factor, the prognosis for future Soviet agricultural output growth seems quite favorable.

The substitution elasticities reported above tell us that the output elasticity of capital, for

all crops but sugar beets, is expected to rise relative to both land's and labor's. For grain and potatoes, a further boost to output growth occurs because land's output elasticity is rising relative to labor's. As it turns out, an optimistic prognosis for the growth of output exists for all crops except sugar beets, where low positive mean σ_{LK} and σ_{RL} signal the ascendancy of labor's output elasticity relative to those of the other two inputs. This generally favorable forecast is more than a little surprising.

A number of other observations might be made concerning the substitution elasticities. The high substitution elasticity between land and labor in grain production is especially interesting in the light of the New Lands Program of the Khrushchev era. This program was characterized by the sowing to grain of immense tracts of previously uncultivated land in Kazakhstan (Central Asia). It permanently changed the regional distribution of Soviet grain production, as evidenced by the fact that, in 1979, the grain harvest in Kazakhstan, for the first time ever, exceeded that of the Ukraine, the traditional Soviet "breadbasket."

The New Lands Program may be seen, in part, as the substitution of plentiful Central Asian land for scarce labor. It also was an attempt to increase production in areas where labor is more plentiful than in the European USSR (of which Kazakhstan is an example). As Gustafson has noted, "Khrushchev in his memoirs claimed that he too favored intensification [that is, a program of raising yields in the European USSR as opposed to opening up new lands elsewhere], but that the country lacked the necessary supporting industrial base . . . and *skilled manpower*" (p. 48). Our finding of a high substitution elasticity between land and labor in grain production demonstrates that this program was based on sound technological grounds. This is another surprisingly favorable empirical finding.

Finally, one might speculate about why the output elasticity of capital, for all crops but sugar beets, has remained significantly positive even as capital intensity has risen. The successive replacement of each vintage of capital equipment (e.g., tractors) with an improved version may help to explain this occurrence. Relative to the Tenth Five-Year Plan (1976–1980), Carey has observed,

> The retirement rate for tractors dropped sharply in 1975. Lower retirement rates would allow faster-than-normal expansion of [machine] parks despite the slower growth of deliveries. Also the trend to larger tractors with greater horsepower and the recent introduction of new combine models will allow parks to be qualitatively improved. (p. 592)

Continuous improvement in the qualitative aspects of capital equipment may account, at least in part, for the presence of a high marginal product of capital for virtually every crop.

Conclusions

In this paper, estimates of production functions for five Soviet agricultural commodities have been presented. Some evidence on technical questions, such as the possibility of using a technological change term to unbias coefficient estimates, has been presented. More important, empirical evidence has been reported on a number of pivotal questions of Soviet agricultral policy. In general, our findings are surprisingly supportive of the appropriateness of Soviet decisions; large farms do seem to be more efficient, land-labor substitution is possible, and the outlook for output growth is good for most crops. This is true despite strong evidence of microeconomic irrationality in Soviet factor pricing.

The last several years have been poor ones for Soviet agriculture, especially for grain (where there were very small harvests in 1977, 1979, and 1980), and sugar beets (which have been disappointing in every year since 1977). The findings of this paper suggest the following (tentative) conclusion: Whatever accounts for the dismal performance record of Soviet agriculture, its problems do not seem to be endemic to the technology of production.

The search for an explanation must lead elsewhere, perhaps to that illusive and uncontrollable, but extremely important, productive input, the weather. Meterological factors, subsumed in the normally distributed disturbance term, may very well account for the extreme annual variation in Soviet crop (especially grain) production. If so, and if, as suggested by the results of this paper, there are no obvious technological limitations which would make Soviet institutional choices inappropriate, then a major reappraisal of Western conventional wisdom on this subject is surely in order.

Multiattribute Utility Analysis: The Case of Filipino Rice Policy

Gordon C. Rausser and Joseph Yassour

Major uncertainties and conflicting objectives often arise in public-policy analysis. This paper advances a framework that is appropriate for public policy problems frequently encountered in agriculture and food systems. Among other possible benefits, its principal value is to provide focus on the major conflicts, trade-offs, and subjective perceptions among affected groups. It can be used to isolate major disagreements, needed empirical evidence, appropriate degrees of risk aversion, equity value judgments, and consensus solutions. In an empirical setting, the framework is used to evaluate price policy for rice in the Philippines.

Key words: multiattribute utility analysis, Philippine rice system, public policy, risk aversion.

Agricultural public agencies generally are charged with the responsibility for meeting the needs and desires of different groups. These groups include producers, consumers, the government, suppliers of inputs, intermediaries (assemblers and distributors), and landowners. Hence, it is not surprising that these agencies have more than a single objective by which to evaluate their effectiveness. The evaluation of trade-offs among the resulting multiple objectives is confounded by major uncertainties found in most agricultural commodity systems. Weather conditions, pests, and diseases introduce significant yield variability. Frequently, low demand and supply elasticities compound the effect of such variability on market price uncertainties.

The purpose of this paper is to demonstrate empirically how a stochastic, multiple-objective, decision-making framework can be operationally useful for public agencies. The first part of the paper describes the general model for optimization under uncertainty and multiple objectives. This model is then applied to determine the optimal price policy for rice in the Philippines.

Model and Methodology

The paradigm for decision making under uncertainty and multiple objectives has been referred to as multiattribute decision analysis (Keeney and Raiffa). This approach consists of two major components: the decision tree and the objective function. Decision trees are flow diagrams which illustrate problems as a chronological arrangement of choices that are controlled by the decision maker and those determined by chance (Raiffa). The probability distributions assigned to chance events can be based on historical data, regression analysis, econometric modeling, or—as often happens—the subjective perceptions of the decision maker.

The most difficult task in multiattribute decision analysis is to determine the appropriate objective function. The least restrictive objective function is the expectation of the multiattribute utility function (MUF):

$$(1) \qquad Eu(x_1, x_2, \ldots, x_n).$$

The construction of such a function involves the following steps: (*a*) prepare a list of objectives (*b*) select a performance measure or attribute for each objective; (*c*) determine

The authors wish to thank Stanley R. Johnson and two anonymous reviewers for offering a number of interesting insights and helpful suggestions in revising the initial version of this manuscript.

whether special independence relationships hold among the performance measures allowing simplification of the MUF; (*d*) assess—if such independence relationships hold—the univariate utility function for each performance measure, $u_i(x_i)$; (*e*) determine the scaling constants (weights) of the univariate utility function in the multivariate objective function; and, finally, (*f*) compute the expected utility.

It is crucial to identify clearly the major objectives of the agency in question. Most often, objectives are vaguely identified. The most common objectives of agricultural public agencies are (*a*) increased income of farmers, (*b*) increased welfare of consumers, (*c*) self-sufficiency, (*d*) price stability, (*e*) improvement in the balance of payments, (*f*) decreased operational expenditures, and (*g*) stable flow of supply.

The performance measure or attribute associated with each objective must be quantified. The measures should be simple and meaningful to the users of the model. This is particularly important because the users must provide utility functions for each of the attributes, independence relationships, and weights for the MUF. Because this task is sufficiently complicated with simple performance measures, overly sophisticated or theoretical measures should be avoided. The construction of the objective function relies heavily on the preference structure and thus the degree of risk aversion of the decision maker. It requires a thorough interviewing process.

If independence exists among the performance measures, then such relationships can be used to specify the appropriate form of the MUF. For simplicity, analysts often assume additive independence relationships. However, other independence relationships can exist and can be used as a basis for more general forms of the MUF. Three types of independence relationships are examined: preferential independence, utility independence, and additive independence. The form of the objective function depends on whether all or some of these relationships exist. In what follows, each type of independence will be defined and its implications for the form of the objective function will be drawn.

The set of attributes A is preferentially independent of set B if preferences over set A do not depend on the amounts in B. Preferential independence is not reflexive. Set A is utility independent of set B if preferences over lotteries on (a, b') do not depend on the fixed amount of b'. Utility independence is not reflexive. The set of attributes A and B are additively independent if preferences over lotteries (a, b) depend only on the marginal probability distributions of a and b and not on their joint distributions.

It has been shown by Fishburn and by Keeney that, if additive independence holds among all attributes, the MUF is of the form,

$$u(x) = \Sigma_i k_i u_i(x_i) \tag{2}$$

(additive). If, however, preferential independence and utility independence hold but additive independence does not, the MUF has been shown by Keeney to be of the form,

$$1 + ku(x) = \Pi_i[1 + kk_i u_i(x_i)] \tag{3}$$

(multiplicative), where k_i is the scaling constant for utility function, u_i, and k is the aggregate scaling constant.

If the objective function is separable—additive or multiplicative—the researcher evaluates the risk perception of the decision maker for each of the attributes, i.e., univariate utility functions are assessed. A five-point utility function may be constructed using 50–50 lotteries.[1] The general form of the function (risk-neutral, constant risk-averse, decreasing risk-averse, etc.) also is determined. Using the general form of the utility function and the five-point utilities, a continuous utility function is approximated.

After the independence relationships and the form of the multiattribute utility function are known, the researcher determines the scaling constants or weights of the attributes. These constants are represented by the k and k_i's in equations (2) and (3).

The Case of the Filipino Rice Industry

The agency charged with the responsibility for formulating and implementing rice policy in the Philippines is the National Grains Authority (NGA). In general, the NGA attempts to promote the integrated growth and development of the Filipino rice industry. Specifically, Presidential Decree No. 4 states:

[1] For a good description of the 50-50 lotteries procedure, see Anderson, Dillon, and Hardaker (pp. 70–75). This approach captures the certainty equivalent for a specified lottery by determining the point of indifference between a risky prospect and a sure prospect. The difference between the certainty equivalent and the expected monetary value is the risk premium which is a function of decision maker degree of risk aversion.

NGA shall devise a system by which it can insure the adequacy of supply and stability of consumer prices at levels within the reach of the low-income families while maintaining the announced floor price to assure farmers or producers with a fair return on their investment. The rationale behind this is the fact that grain is a major item in the food basket of Filipino families. Thus, it has a pervasive effect on Philippine society such that the slightest imbalance in its supply and price is felt nationwide.

Five objectives were chosen to represent the rice welfare of the Philippines for the NGA: (*a*) increase rice farmers' net income, (*b*) attain self-sufficiency in rice production, (*c*) increase consumers' welfare, (*d*) stabilize the market price of rice, and (*e*) decrease government expenditures. The selection of these objectives was based on interviews with officials of the NGA. Similar objectives are reported in Barker, Apiraksirikul and Barker, Mangahas, Herdt and Lacsina, and Timmer.

The performance measure for farmers' net income is the average net income of a rice farm in one cycle (wet).[2] The net income was defined as the gross income (sales) minus the variable cost (hired labor and inputs):

$$(4)\quad x_1 = \frac{\sum_{j=1}^{2} M_j[(Y_j h - H_c - H_s)\bar{P}_p - h(\bar{C}L_j + \bar{C}I_j)]}{\sum_{j=1}^{2} M_j},$$

where x_1 is average net income to farmer per cycle (pesos), M_j is number of farms in category j, j is 1 for irrigated farms and 2 for nonirrigated farms, Y_j is yield per hectare in farm of type j (kilograms per hectare), h is average farm size (2.5 hectares), H_c is farm household consumption per cycle (535 kilograms of palay [paddy rice]), H_s is farm household storage in the wet cycle (135 kilograms of palay), $\bar{P}_p$ is the price of palay to the farmer (pesos per kilogram), $\bar{C}L_j$ is cost of hired labor in farm type j (pesos per hectare), and $\bar{C}I_j$ is cost of inputs in farm type j (pesos per hectare). The net income of farmers is defined as the income above the subsistence level. Household consumption and household storage consumed during the dry cycle were subtracted from wet cycle production.

The performance measure for self-sufficiency in rice production is the percentage of the quantity supplied out of the quantity needed to meet the average consumption of the nonrice-farming population (100 kilograms per capita per year),

$$(5)\qquad x_2 = \frac{q_s}{q_n}\,100,$$

where x_2 is the measure for self-sufficiency, q_s is the quantity of rice supplied per capita (kilograms), and q_n is the quantity consumed per capita (kilograms).

A common measure for consumers' welfare is consumers' surplus. Government officials and economists alike face difficulties in assessing a utility function over this measure. In the case of rice in the Philippines, such a measure can be approximated easily. In particular, for a perfectly inelastic demand, the change in consumer welfare is proportional to the change in the price. Because domestic rice demand in the Philippines is reasonably inelastic, a good approximation to consumer surplus performance measure is provided by

$$(6)\qquad x_3 = P_m,$$

where P_m is the price of rice to the consumer. Given this measure, less of x_3 is preferred to more This feature will be reflected by a monotonically decreasing utility function (see equation [11]). We could, of course, define this performance measure as $1 - P_m$ or $1/P_m$, but this is unnecessary, given that the performance measures enter the utility function as arguments.

The performance measure for price variability is the absolute deviation of the consumers' price from the price in the previous season,

$$(7)\qquad x_4 = |P_{m_t} - P_{m_{t-1}}|,$$

where x_4 is the price variability measure and P_{m_t} is the price to the consumer in period t. The common measure for price variability is the standard deviation of the prices. But once again, a simple measure has been chosen which simplifies the assessment of the decision maker's utility function. Moreover, note that this performance measure does not penalize for large deviations from the previous price. If such penalties exist, they will be reflected by the utility function.

The performance measure for government

[2] We distinguish two production cycles of rice in the Philippines—the dry cycle during which only irrigated rice is planted and the wet cycle during which both nonirrigated and irrigated rice is planted. In order to include nonirrigated farms, the period of analysis will refer to the wet cycle. Since the wet cycle covers only half a year, the period of analysis is referred to as a semester.

expenditures (x_5) is the total expenditures per capita of NGA in executing its policies. These expenditures consist of the (*a*) cost of purchasing palay from the farmers, (*b*) plus the cost of importing rice less the revenues from selling rice to consumers, (*c*) less the revenues from exporting rice, and (*d*) plus the transportation, operating, and storage costs.

Empirical Estimation of the Objective Function

Based on an interview with the former administrator of the Rice and Corn Administration and various members of the current NGA, it was found that the five performance measures are pairwise preferential independent and that at least one performance measure is utility independent. It was also found that additive independence did not exist among the performance measures. This implies (Keeney and Raiffa, p. 344) that the MUF, is the appropriate objective function,

$$(8)\quad 1 + ku(x_1, x_2, x_3, x_4, x_5) = \prod_{i=1}^{5} [1 + kk_i u_i(x_i)].$$

Given equation (8), it is necessary to determine the $u_i(x_i)$ and k_i's for $i = 1, 2, 3, 4, 5$.

The univariate utility functions were assessed by determining the certainty equivalents for 50–50 lotteries. More specifically, we set $u_i(x_i^0) = 0$ and $u_i(x_i^1) = 1$, where x_0 and x_1 are the lowest and highest levels each performance measure i can assume. Then we find $x_i^{.5}$, which is equivalent to a 50–50 lottery between x_i^0 and x_i^1. Then, similarly, we find $x_i^{.25}$, which is equivalent to a 50–50 lottery x_i^0 and $x_i^{.5}$; and, finally, we find $x_i^{.75}$. These five points are the basis for fitting a continuous utility function.

Using the procedure described above, we obtained the following univariate utility functions for the five performance measures:

$$(9)\quad u_1(x_1) = 1.01 - 4.29 \exp(-.00125\, x_1),$$

$$(10)\quad u_2(x_2) = -1.12 + 0.54 \ln(x_2 - 68),$$

$$(11)\quad u_3(x_3) = 0.09 + 0.66 \ln(5 - x_3),$$

$$(12)\quad u(x) = 0.72 \ln(4 - x), \text{ and}$$

$$(13)\quad u_5(x_5) = -4.81 + 1.28 \ln(85 - x_5).$$

As casual observation would suggest, the objective performances, x_1 and x_2, are measured as "goods," while x_3, x_4, and x_5 are measured as "bads." In addition, note that the univariate utility function for farmer net income, x_1, reveals constant risk aversion while all other utility functions, as expected, exhibit decreasing risk aversion. Hence, except for farmer net income, the more favorable the level of the performance measure, the smaller the degree of risk aversion. In the case of farmer net income, decreasing risk-averse functions proved to be poor approximations, while the constant risk-averse function fitted the five points very closely and prevented bias estimates of the minimum farmer net income level.

The scaling constants (weights) of the objective function (k_i's and k) were assessed by equating five different combinations of the various performance measures and using equations (8)–(13) to solve the five equations for the five k_i's and then using

$$(14)\quad 1 + k = \prod_{i=1}^{5} (1 + kk_i)$$

to solve for k. The estimated scaling constants (k_i's) were $k_1 = .8$, $k_2 = .58$, $k_3 = .65$, $k_4 = .52$, $k_5 = .33$, and $k = -1$. Thus, the MUF used in the model is

$$(15)\quad u(x_1, x_2, x_3, x_4, x_5) = 1 - [1 - .8u_1(x_1)][1 - .58u_2(x_2)][1 - .65u_3(x_3)][1 - .52u_4(x_4)][1 - .33u_5(x_5)].$$

Note that all x_i's appearing in (15) are random variables. This randomness relates largely to uncertain rice yields (appearing in x_1, x_2, and x_5) and uncertain prices (appearing in x_1, x_3, x_4, and x_5). Over the relevant ranges, the performance measures have the expected effects on $u(\cdot)$. Increases in both x_1 and x_2 result in larger utilities ("goods"), while increases in x_3, x_4, and x_5 lead to smaller utilities ("bads"). In all instances, except for x_3, these outcomes conform to conventional treatments; increases in farmers' net income (x_1) and production self-sufficiency (x_2) and decreases in price instability (x_4) and government expenditures (x_5) lead to improvements in multiattribute utility. The apparent perverse outcome for the proxy consumer welfare performance measure (x_3) is simply because x_3 is the negative of the consumer well-being measure.

From (15), the trade-offs among the various performance measures can be derived. Because of the preferential and utility indepen-

dence properties of (15), each trade-off is a variable measure of only its own performance levels. For example,

$$(16)\quad \frac{dx_1}{dx_3} = \frac{.0824 + 1.4723e^{(-.00125x_1)}}{(5 - x_3)(-.00429e^{-.00125x_1})} [.9415 - .43 \log (5 - x_3)].$$

The sign on this trade-off is, as expected, $dx_1/dx_3 > 0$; thus, for a constant level of multiattribute utility and all other performance measures, an increase in x_1 must be accompanied by an increase in x_3. The remaining trade-offs over the relevant ranges are $dx_1/dx_2 < 0$, $dx_1/dx_4 > 0$, $dx_1/dx_5 > 0$, $dx_2/dx_3 > 0$, $dx_2/dx_4 > 0$, and $dx_2/dx_5 > 0$, $dx_3/dx_4 < 0$, $dx_3/dx_5 < 0$, and $dx_4/dx_5 < 0$.

Alternative Price Policies

The price policy for rice consists of determining the floor price to the producers (pesos per kilogram of paddy), ceiling price to the consumers (pesos per kilogram of rice), and reserve stock policy. Only the different alternatives of floor and ceiling price will be evaluated. In particular, three forms of NGA intervention will be examined, namely, (*a*) "free market" or no floor or ceiling price policy, (*b*) "complete" intervention under which NGA would import (export) the quantity necessary to drive the market price down (up) to the ceiling (floor) price, and (*c*) "limited" intervention under which NGA attempts to satisfy various forms of free enterprise constraints.

Domestic prices of paddy to producers and consumer rice prices are, of course, uncertain. These uncertain prices depend upon a number of other uncertainties including farm yields, consumer demand, farmers' response, the world market price, and the form of NGA intervention. The free market form involves no domestic price limits, while form (2) requires setting a floor price to producers (P^*_p) and a ceiling price to consumers (P^*_m). For the latter policy intervention scheme, domestic prices are determined by the intersection of consumer demand and producer supply and the margin of the intermediaries, bounded by P^*_p and P^*_m. Because there is empirical evidence that the margin between the retail and the farm price is more or less constant (Castillo; Mangahas, Recto, Ruttan; Mears et al.; Yassour), a fixed margin (P_i) of .45 pesos per kilogram may be imposed.

For complete NGA intervention, policy implementation depends upon two distinguishable cases: (*a*) the floor price to producers plus the intermediaries' margin is greater than or equal to the ceiling price to the consumers,

$$(17)\quad P^*_p + P_i \geq P^*_m,$$

and (*b*) the floor price plus the intermediaries' margin is lower than the ceiling price,

$$(18)\quad P^*_p + P_i < P^*_m.$$

For (*a*), NGA has to intervene regardless of the market behavior. It is assumed that, for those policies which imply relation (17), NGA will subsidize the rice by the amount ($P^*_p + P_i - P_m$) for a kilogram consumed domestically. If the quantity locally supplied is greater (smaller) than needed to meet the ceiling price, NGA will export (import) the surplus (deficiency). Note that, for any level of P^*_m and a particular demand function, there is a corresponding level of q^*_m or quantity (per capita) marketed necessary to achieve the ceiling price. In this instance, $P_m = P^*_m$ and $P_p = P^*_p$, and governmental expenditures are determined by

$$(19)\quad x_5 = q^*_m(P^*_p + P_i - P^*_m) - (q_s - q^*_m)(\delta r P_x - P^*_p - P_i),$$

where P_p is the actual price of rice to the farmer (pesos per kilogram), P_m is the actual price of rice to the consumer (pesos per kilogram), q_s is the quantity locally supplied per capita (kilogram per capita), P_x is the world market price for rice CIF Manila (dollars per kilogram), r is the rate of currency exchange (pesos per dollar), and δ is 1 if $q_s \leq q^*_m$ (CIF) and 8 if $q_s > q^*_m$ (FOB). The first component of the left-hand side of the government expenditures equation is the subsidy paid by the government, and the second component is the revenues (costs) from exporting (importing).

In case (*b*), where relation (18) applies, the market equilibrium is allowed to play a crucial role. In this setting, three possible market scenarios are distinguishable. Scenario 1 is when $P_e < P^*_m$ and $P_e - P_i < P^*_p$, where P_e is the equilibrium price at the consumer level. For this scenario, the consumers' side is satisfied but not the producers'. Hence, in order to meet the floor price to the producers, NGA purchases and exports enough to maintain the domestic floor price. In this instance, NGA would export the quantity $q_s - q^*_p$, $P_p = P^*_p$, $P_m = P^*_p + P_i$, $P_m < P^*_m$, and

$$(20)\quad x_5 = (q_s - q^*_p)(P^*_p + P_i - .8rP_x),$$

where q^*_p is the quantity marketed necessary to meet the floor price for the realized demand function.

Scenario 2 is when $P_e < P_m$ and $P_e - P_i > P^*_p$. In this scenario, since both sides are satisfied, NGA would not intervene in the market. The prices would be $P_m = P_e$, $P_p = P_e - P_i$, and government expenditures would be zero.

Scenario 3 is when $P_e > P^*_m$ and $P_e - P_i > P^*_p$. For this scenario, the producers' side is satisfied but not the consumers'. In order to meet the ceiling price to the consumers, NGA would import the quantity $q^*_m - q_s$. Prices would be $P_m = P^*_m$, $P_p = P^*_m - P_i$, $P_p > P^*_p$, and government expenditure is determined by

$$(21) \qquad x_5 = (q^*_m - q_s)(rP_x - P^*_m).$$

For limited forms of NGA intervention, policies are constrained by desires to keep the amount of involvement in the private sector at some minimal satisficing level. These forms of intervention presume that NGA is reluctant to implement a policy which implies fixed prices to farmers and consumers and an associated large subsidy program. Since limited involvement in the rice industry of the Philippines was not treated as one of the measurable objectives, trade-offs between the rate of governmental involvement and the other performance measures are not available.[3]

Three specifications of the limited involvement constraint will be examined. The first severely limited NGA involvement by requiring no direct government subsidies. Recall that direct government subsidies are required whenever the consumer price is lower than the farm price plus the intermediaries' margin. Hence, no direct government subsidies are required when $P^*_p/.61 + P_i < P_m$, where .61 is the rate of recovery from paddy to rice. A second specification limits the producer floor price to no more than 1.20 pesos per kilogram, i.e., $P^*_p \leq 1.20$. Finally, a third specification combines these two constraints as the satisficing levels for the limited involvement objective. Note that, for each of these specifications, the shadow price of the corresponding constraint may be computed; on the basis of these computations, NGA and the government of the Philippines can make an informed judgment of whether or not the corresponding limited involvement objective justifies its costs.

[3] The constraints implied by the desire for such limited involvements may be regarded as the highest objective in a lexicographically ordered criterion function with the second objective measured by the MUF (15); i.e., given the satisfaction of a limited involvement constraint, proceed to maximize $EU(x_1, x_2, x_3, x_4, x_5)$.

Uncertainty: Weather

A subjective probability distribution was assessed for the nature conditions variable with three possible outcomes: "bad"—production is 10% below normal; "moderate"—production is normal; and "good"—production is about 10% above normal. Based on the assessments of NGA officials, agricultural economists, and farmers, the probability distribution used in the analysis was good nature conditions, $p = .2$; moderate nature conditions, $p = .5$; and bad nature conditions, $p = .3$. A more objective analysis of rice yields (Yassour) resulted in a similar distribution.

Uncertainty: Farmers' Response

Two types of farms are distinguished here: irrigated and nonirrigated. For the irrigated farms, the farmers usually grow more than one crop per year; these are less vulnerable to nature conditions and are more profitable. The nonirrigated farms, however, are less intensively cultivated. Most of them are in areas far from the big marketing centers and are less flexible in their marketing options.

NGA officials and Filipino agricultural economists have been asked to assess the response of farmers who grow rice in irrigated and nonirrigated farms to different levels of floor price for paddy. Their assessments are summarized in table 1.

Uncertainty: Demand

Uncertain demand arises with respect to both its functional form and the price elasticity. The uncertain functional form was admitted by specifying both linear and Cobb-Douglas forms. In the case of price elasticities, the findings of Mears, Nasol, and Apiraksirikul show that the price elasticity of demand for rice in the Philippines ranges from $-.2$ to $-.5$. By substituting the current quantity consumed per capita per year (100 kilograms) and the current consumer price (2.10 pesos per kilogram) in linear and Cobb-Douglas functions, the respective demand functions were obtained. A subjective probability distribution was then assigned over the elasticities. This was done with the advice of the researchers in the Department of Agricultural Economics of

Table 1. Subjective Assessments of Probability Distributions of Farmers' Response to Different Levels of Floor Price

	Probability					
	Irrigated			Nonirrigated		
Floor Price	.25	.5	.25	.25	.5	.25
	(% of production[a])					
1.00 peso per kilogram	92	97	102[b]	95	98	101
1.10 pesos per kilogram	100	100	100	100	100	100
1.20 pesos per kilogram	102	104	106	100	101.5	103
Free market[c]	99	100	101	97	99	101

[a] Farmers intend to grow 100% production under the current floor price (1.10 pesos per kilogram). This basic figure differs for irrigated and nonirrigated farms.
[b] Higher production for lower price was explained by the fact that there is a group of farmers who place a high value on leisure time. The quantity those farmers produce is that which is sufficient to cover their basic needs. Prices at the level of 1.00 peso per kilogram force them to produce more in order to meet their subsistence level.
[c] This row represents the subjective assessment of how farmers would behave if the floor price policy were terminated and the free market would operate to determine producer prices.

the University of the Philippines, Los Banos, and of the International Rice Research Institute. The elasticities to be analyzed in the model, their respective demand functions, and their probabilities are shown in table 2.

In order to avoid skyrocketing prices for very small quantities as a result of an exponential demand function and negative prices for very large quantities as a result of a linear demand function, the demand function was specified as linear to the left of the current quantity consumed (100 kilograms per capita per year) and exponential to its right.

Uncertainty: World Market Price of Rice

The price NGA would pay (receive) for imported (exported) rice is also a random variable. Based on their knowledge about the situation of rice and grains in the international market, NGA officials provided the probability distribution shown in table 3 for the year 1978.

The prices in table 3 include the cost of the rice itself, sea transportation and insurance, and transportation from the port to the warehouse. The price that NGA would receive for one ton of exported rice (FOB) is, of course, lower. NGA officials estimated that, for the same quality of rice, the export price per ton would be lower than the import price by about 20%.

Empirical Results

The NGA decision problem under the uncertainties discussed above is shown in decision-tree form in figure 1 for cases of $P^*_p = 1.20$ and no intervention.[4] At each end point of

[4] The following data were used in analyzing the model: average family size of a rice-growing farm is 6.5 (Hayami et al.); current yearly consumption of rice is 100 kilograms per capita (Aviguetero): rate of recovery from palay to rice is .61; wet season production is 62.5% of the total yearly production; yield of irrigated and nonirrigated farms is 2.25 and 1.5 tons per hectare, respectively (45 and 30 cavans per hectare); the number of irrigated and nonirrigated farms is 360,000 and 600,000, respectively, with an average farm size of 2.5 hectares; current price to consumers is 2.10 pesos per kilogram (Alix, Kunkel, Gonzales); cost of labor per irrigated and nonirrigated hectare is 400 pesos per hectare and 300 pesos per hectare, respectively; cost of inputs is 400 pesos per hectare and 250 pesos per hectare, respectively (NGA files); and exchange rate is 7.3 pesos per dollar.

Table 2. Price Elasticities of Demand for Rice, Demand Functions, and Probabilities

	Demand Function		
Price Elasticity	Exponential	Linear[a]	Probability
−.2	$P = (116/q)^5$	$P = 12.60 - .105q$	.3
−.3	$P = (125/q)^{3.33}$	$P = 9.10 - .07q$	.3
−.4	$P = (135/q)^{2.5}$	$P = 7.10 - .05q$	.3
−.5	$P = (145/q)^2$	$P = 6.10 - .04q$	.1

[a] The linear demand functions are the linear approximations of the exponential functions at the region of the current price and quantity consumed per capita.

the decision tree for these as well as all other alternatives, we have the levels of each performance measure, x_i. These performance measures depend on the policy and the relevant uncertainties, reflected by probability measures representing the chance of reaching a particular end point. The values of the five performance measures, together with the univariate utility functions (9)–(13) and the probability distributions, are then used in (15) to compute the expected utility for each policy. The analysis was conducted for feasible floor prices ranging from 1.00 to 1.50 pesos per kilogram of paddy and ceiling prices ranging from 1.70 to 3.10. This was done for the complete and limited forms of NGA intervention.

A complete intervention policy involving a floor price set at 1.40 and a ceiling price set at 2.10 maximizes expected utility; for this policy, $EU = .96984$. For a .61 rate of recovery from palay to rice and an intermediaries' margin of .45 peso, this policy generates a price at the consumer level of 2.74 and thus implies a subsidy of .64 peso per kilogram. This policy, along with the limited intervention policies, proved superior to the free market policy which generated an expected utility of .95569.

For the "limited" involvement of no direct government subsidies, i.e., $P^*_p/.61 + P_i < P_m$, the optimal solution is $P^*_p = 1.30$ and $P^*_m = 2.90$, which generates an expected utility of .96696. For the second limited involvement specification, i.e., $P^*_p \leq 1.20$, the optimal policy is $P^*_p = 1.20$ and $P^*_m = 2.10$, with expected utility falling to .96678. This policy implies a direct government subsidy of .32 peso

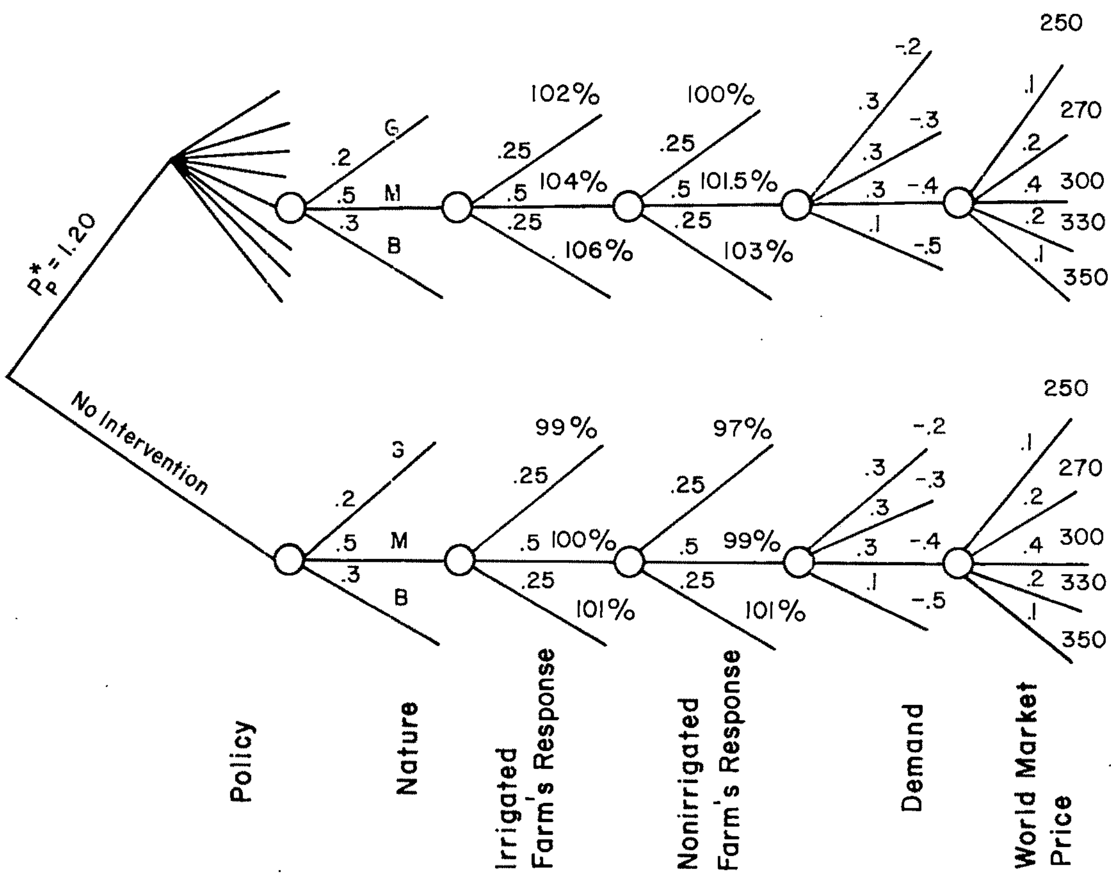

Figure 1. The decision tree

per kilogram of rice. Finally, for both constraints, $P^*_p/.61 + P_i < P_m$ and $P^*_p \leq 1.20$, the optimal policy is $P^*_p = 1.20$ and $P^*_m = 2.90$, and the expected utility is .96675.

A comparison of the various policies reveals small differences in the expected multiattribute utility. This is due to the assessment procedure of the Keeney and Raiffa approach, which bounds U between zero and unity. The small differences may imply large movements in the certainty equivalents for each performance measure, x_i. In sorting out the implications of the expected multiattribute utility in terms of the individual performance measures, however, some obvious difficulties arise. The scaling constants, multiple performance measures, trade-offs, and associated univariate utility functions complicate the relationship between EU and any particular x_i. To obtain consistent results, one way to proceed would be to fix the level of four performance measures and, given EU, solve equation (15) for the remaining performance measure.

For example, fixing x_2, x_3, x_4, and x_5 at levels for which $u_i(x_i) = .84$, $i = 2, 3, 4, 5$, where the value .84 for $EU_i(x_i)$ was chosen to stay within the original range of the attributes, we can derive the complete intervention expected utility equivalent measure for x_1. It is $x^*_i = 2{,}642$. Proceeding in this fashion, expected utility equivalents for the remaining x_i's can be obtained for each policy. These results are reported in table 4. Note that a higher floor price results in a lower expected-utility-equivalent measure for governmental expenditures. This is because all the gains from increased floor prices (namely, farmers' net income and self-sufficiency) are translated into savings in the governmental expenditure policy equivalent measure. To be sure, increased floor prices lead to larger actual governmental expenditures; but the gains in other performance measures, when translated into the utility equivalents for government expenditures, more than compensate for its actual increase.

The above approach allows policy debate to take place in terms of individual performance measures—namely, their utility equivalents—rather than the more obscure multiattribute utility measures. For example, in comparing the current policy (1.10, 2.10) with the maximum floor-price, limited intervention policy (1.20, 2.10), the difference in expected utilities will have little meaning to policy makers. However, a "utility equivalent" difference of 39.5 pesos less 11.5 pesos per capita, or 1,232 million pesos for the total population, is more revealing.[5] This means that, in terms of the criterion function (15) incorporating all performance measures, a utility equivalent comparison of government expenditures results in savings of 28 pesos per capita. Similar multiattribute utility comparisons can be made in terms of the remaining performance measures.

Sensitivity Analysis

Sensitivity analysis was conducted for a number of important variables. As expected, it was found that higher expected utilities resulted in

[5] The figure 11.5 pesos per capita was derived by substituting .96678 for EU on the left-hand side of (15) and .84 for all $EU_i(x_i)$, $i \neq 5$, thus obtaining $EU_5(x_5) = .69$. Substituting the computed value .69 into (13), we find $x^*_5 = 11.5$ pesos per capita. A similar procedure is followed for all expected utility equivalent measures, x^*_i.

Table 4. Comparisons between Current, Complete, and Various Limited Forms of NGA Intervention

	Current Policy [1.10, 2.10]	Complete [1.40, 2.10]	Limited: No Direct Subsidies [1.30 2.90]	Limited: Maximum Floor Price [1.20, 2.10]	Limited: Maximum Floor Price and No Direct Subsidies [1.20, 2.90]
Expected utility	.95809	.96984	.96496	.96678	.96675
Value of:[a]					
x^*_1 (pesos)	2,095	2,642	2,470	2,460	2,458
x^*_2 (%)	89.3	107.6	102.0	101.7	101.6
x^*_3 (pesos/kg.)	2.84	1.78	2.08	2.10	2.11
x^*_4 (pesos/kg.)	2.10	.64	1.08	1.10	1.11
x^*_5 (pesos per capita)	39.5	−1.9	10.8	11.5	11.7

[a] The values of x^*_i result in the above expected utility when the values of the other performance measures are fixed such that $u_j(x_j) = .84$, $j \neq i$ ($x_1 = 2{,}853$ pesos, $x_2 = 105.7\%$, $x_3 = 1.38$ pesos/kg., $x_4 = .79$ pesos/kg., and $x_5 = 2.40$ pesos per capita).

lower consumption, decreased population, higher yields, more rice farms in general, and more irrigated farms in particular. Generally speaking, the floor price of the optimal policy decreased as the total production increased. Because of space limitations, we report here only the sensitivity analysis performed on the responsiveness of farmers to changes in the floor price and the potential instability in the trade-offs among alternative performance measures. Because the sample data did not include a floor price above 1.20 pesos per kilogram, a number of alternative assumptions were investigated. The results for the conservative assumption that farmers' response to floor prices above 1.20 pesos per kilogram would be the same as for 1.20 pesos per kilogram clearly indicate that a 1.40 floor price and 2.10 ceiling price for the complete intervention scheme dominates all alternatives examined (floor prices range from 1.00 to 1.30 pesos per kilogram and ceiling prices from 1.70 to 3.10 pesos per kilogram). The second-best policy was [1.50, 2.10].

With respect to potential instability in performance measure trade-offs, significant changes in NGA membership composition or interest group influence will be reflected in the scaling constants. Initially, these constants were determined as follows: $k_1 = .8$, $k_2 = .58$, $k_3 = .65$, $k_4 = .52$, and $k_5 = .33$. In the sensitivity analysis, all 243 possible combinations of $k_1 = .9, .8$, and $.7$; $k_2 = .7, .6$, and $.5$; $k_3 = .75$, $.65$, and $.55$; $k_4 = .6, .5$, and $.4$; and $k_5 = .45$, $.35$, and $.25$. Of the 243 combinations examined, 75 resulted in [1.50, 2.10] as the best policy; 47 in [1.40, 2.10]; 26 in [1.30, 2.10]; and 21 in [1.20, 2.70]; the remaining 74 combinations resulted in seven other policies. The optimal policy was sensitive mainly to the values of k_1 and k_5.

Conclusion

This paper illustrates an approach to public policy analysis emphasizing uncertainty and conflicting objectives. The framework seems especially appropriate for public policy problems frequently encountered in agriculture and food systems. Its principal value may be to provide focus on the major conflicts, trade-offs, and subjective perceptions among affected groups. It can be used to isolate major disagreements, needed empirical evidence, appropriate degrees of risk aversion, equity value judgments, consensus solutions, and the like.

Determining price policy for rice in the Philippines served as an illustration of the framework. Here, the optimal complete intervention policy consisted of a floor price of 1.40 pesos per kilogram and a ceiling price of 2.10 pesos per kilogram. This policy implies fixed farm and retail prices and a subsidy of .64 pesos per kilogram. Such a policy requires major changes in NGA operations and administration. Moreover, it contradicts free-enterprise ideals. Therefore, as a first stage, NGA might implement a policy in which the floor price is 1.30 pesos per kilogram and the ceiling price is 2.70 pesos per kilogram. This does not imply fixed prices or direct government subsidies ($1.30/.61 + .45 < 2.70$). A ceiling price of 2.70 pesos per kilogram at the farm may result in a sharp increase in the consumer price. The probability of such an increase, however, is lower under the suggested policy than under the current policy. This is because of the expected higher production occurring response to the higher floor price. In the unlikely case of a nationwide disaster, NGA could launch a temporary emergency program of direct government subsidies.

Predicting the Diffusion of Improved Pastures in Uruguay

Lovell S. Jarvis

Research suggests the logistic curve is the characteristic diffusion path for new technologies. Econometric analysis of fertilized grass-legume pastures in Uruguay indicated that their diffusion during the first years following introduction also followed a logistic path. Some departure from a simple logistic shape was explained by including beef and fertilizer prices within the diffusion framework. Both the rate and limit of diffusion were positively related to changes in the technology's profitability, but the estimated price elasticity of each was low. Extrapolation predicted that a ceiling equal to 12% of Uruguayan pasture area would be reached in 1980.

Key words: diffusion, logistic curve, new technology, pastures, prediction, Uruguay.

This paper analyzes the diffusion of improved pastures in Uruguay, a development promoted since 1961 by a joint Government of Uruguay/World Bank lending and technical assistance project (Hirschman, Jarvis 1976). The cumulative growth in the number of ranchers who have adopted this technology and total area planted to improved pastures is explained by fitting the diffusion data to logistic curves. However, the diffusion process is analyzed before diffusion has ceased. Total diffusion and the date at which the ceiling is achieved are predicted using observations from the first years of the process. Beef and fertilizer prices are incorporated into the analysis to obtain improved estimates of future diffusion.

The introduction of fertilized grass-legume pastures increased livestock output about 18% between 1961 and 1975, two-thirds of the entire increase (Jarvis 1976). Fertilized grass-legume pastures are the principal, feasible means to higher Uruguayan livestock production and exports. Annual gross pasture investments rose from 18,000 hectares in 1961 to 320,000 hectares in 1973, the historical peak. Cumulative net pasture improvements reached 1.64 million hectares in 1975, 11.5% of the total pasture area (table 1). By 1975, total adopters numbered more than 15,000, or more than half the potential (table 1). Nonetheless, the increase in area planted to improved pastures has been slower than hoped. Improved pasture use is still much less than in New Zealand (62% of pasture area), the source of this particular technology.

In 1975, the rate of pasture investments was declining. A sharp decline in beef prices had occurred, making the two phenomena appear related. Some experts believed that a recovery of beef prices would cause a recovery in pasture investments. Because this belief was important for government policy and relevant to future World Bank lending in Uruguay for livestock development, the following hypotheses were tested. (*a*) The rate and the limit of technology diffusion can be predicted with information from the first years following introduction. (*b*) The rate and the limit of diffusion are positively related to changes in the technology's profitability.

The Model

Several studies analyze the diffusion of new technologies, e.g., Griliches and Mansfield. Because these studies observed a characteristic diffusion path, I wanted to determine if the diffusion of improved pastures in Uruguay followed the same pattern. If so, perhaps the

future of pasture investments could be predicted by extrapolation. These studies showed that the cumulative adoption path often behaves like a logistic curve (fig. 1). Diffusion begins when the technology first becomes available (t_0). The number of adopting producers increases slowly at first, because only the most progressive and/or less risk-averse adopt. Then it increases more rapidly as information spreads to other producers. Finally, it slows when nearly all producers who will find the technology profitable have adopted, the process reaching an essentially stable ceiling (t_-).

The logistic function traces diffusion toward an equilibrium by assuming that the technology's profitability remains constant. Because diffusion often requires twenty years, it would be surprising if changes in prices, technology, and learning over time did not seriously affect the diffusion process and distort its profile away from a simple pattern. The issue is worth further research. In this paper, the logistic is accepted as a starting point because of its mathematical simplicity. However, some departure from a simple logistic shape will be explained by including other variables within the diffusion framework.

The logistic curve is defined as follows:

$$Z_t = \frac{K}{1 + e^{-c-\phi t}}, \tag{1}$$

where Z_t is cumulative number of adopters by time t; K is ceiling, i.e., the total ranchers adopting by the time the diffusion process ceases ($[K/T]$ is the final percentage of the ranchers expected to adopt, where T is total potential adopters); ϕ is the rate at which diffusion occurs; and c is a constant term.

Previous economic studies attempted to show that diffusion conformed to the logistic shape and that variations in the diffusion rate and the ceiling reached (among different processes) were related to observed economic variables. Analysis occurred after diffusion had ceased and a stable ceiling was observable. Thus, only the diffusion rate was estimated. In this study, because the ceiling had not been reached, both the ceiling and the rate of diffusion were estimated simultaneously.

Characterizing the Diffusion of Improved Pastures
